GENITAL CHANCRES IN WOMEN.\*

By R. W. TAYLOR, M. D.,

CLINICAL PROFESSOR OF VENEREAL DISEASES  
AT THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

CHANCRES of the genital organs are very common in men and in women, but in the latter extra-genital chancres occur much more frequently than they do in men.

Our knowledge of genital chancres in the female is far from complete, and this essay is offered with the hope of presenting a succinct and graphic description of these lesions, together with life-like pictures of them.

Chancres in women are far less regular in their course than they are in men. In many women the chancre is so small, benign, and ephemeral that it may never be seen, or, if seen, its nature is usually not suspected. In very many cases, even when the lesion is strikingly apparent, its nature remains for a long time in doubt, owing to inflammatory complications and to a want of striking individuality in the lesion itself. Then, again, simple inflammatory processes and chancroidal ulcers often become upon the female genitals so complicated and obscure in appearance that they may resemble specific lesions. In women, induration as a symptom is not so generally observed as it is in men. In some females it can scarcely be appreciated by careful examination, and it may be very transitory in its duration, whereas in others it attains large proportions, lasts for indefinite periods, and may lead to ultimate deformity. In men the chancre is readily examined. In women this lesion, owing to the nature and inaccessibility of the parts, is very difficult of examination except on protruding portions of the genitals.

The main reason why chancres in the female are so little understood, are so frequently unrecognized, and generally offer so much difficulty in diagnosis, is that there is very little chance for their study on a large scale, and faithful pictures of them are not obtainable.

As in men so in women, the chancre is simply a localized aggregation of a peculiar new specific cell growth. For certain purposes we may divide genital chancres in women into the following varieties:

1. The superficial or chancreous erosion.
2. The sealing papule or tubercle.
3. The elevated papule or tubercle (exulcerated), ulceratum.
4. The incrustated chancre.
5. The indurated nodule.
6. The diffuse exulcerated chancre.

*The Superficial Erosion, also called the Chancreous Erosion.*—The most constant early appearance of the syphilitic chancre in women is seen in the form of an erosion of the mucous membrane. In its very early days this lesion presents no well-marked characteristics and is very liable to be

mistaken for a ruptured herpetic vesicle, an abrasion, chafe, or scratch. Such is its seemingly benign, superficial, and aphlegmasic character and small size that its nature is frequently not determined at the first examination. Indeed, as Fournier says, "nine times out of ten the nascent chancre is not recognized as such."

The chancreous erosion is always found on the surface of the mucous membrane. It begins as a red spot, somewhat deeper in color than the mucous surface on which it is seated. It is very rarely, if ever, seen in women in the first few days of its existence, for the reason that its presence is usually unknown to its bearer, or, if it is seen by her, it appears so simple, mild, and harmless that its nature is scarcely ever suspected. Thus it is that when first seen by the physician the red spot has become, by desquamation of its epithelium, an erosion. When seated on smooth surfaces, such as presented by the internal surfaces of the labia majora and the greater part of the labia minora, this lesion, when somewhat advanced, presents certain well-defined features, but when it is developed upon the anfractuous surfaces of the fourchette, the introitus vaginae, the vestibule, and around the urethra, its appearance is not striking, and, indeed, is often misleading to the eye, while its exploration is difficult and unsatisfactory to the fingers. In very many cases a catarrhal or blennorrhagic condition of the parts conduces to further obscurity of the diagnosis.

When the erosion is quite well developed it presents the appearance of a very superficially excoriated lesion, of a more or less deep-red color, resembling quite closely muscular tissue. This color, however, varies in different cases between certain extremes. In very cleanly and anæmic women the redness may be scarcely deeper than normal, while in uncleanly persons, in those suffering from simple or blennorrhagic inflammation of the genital tract, in those in whom the coaptation of the parts is close and tight, and in pregnant women, the chancre may be of an extremely deep dull-red tint.

Upon smooth, tolerably flat surfaces the chancreous erosion is usually round or oval in shape, though either of these outlines may become irregular. On anfractuous surfaces the chancre presents corresponding irregularities. The surface of the chancre is smooth, sometimes even glistening and shining, and shows that the lesion is formed of tolerably compact tissue. It usually presents a solidity of structure which is striking. When seated upon parts in which the chancre is subjected to movement, or in clefts, the smoothness of surface may be more or less lost.

The secretion of the chancre is usually serous in character, but it may also contain some leucocytes. It varies in quantity considerably; from some chancres we see very little serous oozing, while from others it is quite copious. When seated on an inflamed surface, or when the chancre is irritated, it may secrete true pus. In some cases these chancres become contaminated with chancroidal pus, and they are then converted into ulcers whose nature it is very difficult to determine.

The true chancreous erosion scarcely presents an appreciable elevation, and the lesion may run its course and

\* Read before the American Association of Genito-urinary Surgeons, September 22, 1891.

disappear without ever becoming salient above the normal plane.

While in general there is not a well-defined margination of the chancreous erosion, the eye can plainly see where the lesion ends and where sound tissue begins. In some cases, however, the circumferential margin becomes hyperplastic and the chancre is converted into a saucer-shaped lesion. The size of this chancre varies considerably; some reach maturity, and have a diameter of a third or half an inch, and it is not common to see one larger than an inch in diameter.

In many cases, even when a satisfactory examination is possible, no evidence of induration can be made out, and at best soft, œdematous hyperplasia may be felt. In other cases, however, induration of a superficial, flat character—parelment induration—can be felt. This form of chancre is well depicted in Fig. 1.

As already stated, in many instances the chancreous erosion runs its whole course as a non-salient lesion, but in others the erosion lesion gradually develops into a papule or tubercle, the description of which will soon follow.

While in general the chancreous erosion is with difficulty diagnosed in its early days, if it is protected from irritation and dirt and carefully watched, its nature may be determined in the course of ten days or two weeks, if not sooner. Herpetic discs, chafes, and excoriations usually show a tendency to become rapidly cicatrized by the simple interposition of lint or of a mild astringent wash, and from the first they show signs of healing. On the other hand, despite judicious aseptic measures, the chancreous erosion keeps on its course without any early signs of healing. With this lesion the implication of the ganglia can usually be well made out in about two weeks, and this sign, with the typical appearance of the lesion, will usually make the diagnosis of syphilis clear.

Chancreous erosions, when seated upon the surfaces of the labia, large and small, are very commonly multiple, varying in number from two to four.

The chancreous erosion upon uneven and anfractuous surfaces is even more difficult of recognition than the lesions just considered. Upon the carunculæ myrtiformes, about the urethra, at the fourchette, and around the vaginal orifice the lesion rarely has a definite shape and outline. As Clerc says, the syphilitic neoplasm molds itself to the parts it is seated upon, and when these parts are uneven, nodular, fringed, and anfractuous, its shape, outline, and general configuration are vague and indeterminate. The diagnosis at best being very difficult, it is often rendered more obscure and even impossible by underlying chronic and acute inflammatory conditions of the vagina and vulva. I have many times seen this form of chancre thus located pass wholly unrecognized by careful and skilled men in the cases of women suffering from simple and blennorrhagic inflammation of the genitals. In practice the best course to pursue when one is consulted for or sees a deep-red, superficially eroded patch, or even papule of irregular outline on the parts just mentioned, is to keep them free from all irritation and apply a bland lotion on cotton. If the lesion is simple in character, it will soon become

pale and heal, but if it is composed of syphilitic cell-growth it will keep on and become further developed. Time, watchfulness, and the condition of the ganglia will within three weeks certainly make the diagnosis clear. It follows, therefore, that the physician should speak guardedly of these lesions, and that he should never pass them over as insignificant or pronounce them off-hand as being of no moment.

A frequent and striking peculiarity of the chancreous erosion is its short period of existence. It frequently comes and goes without the knowledge of its bearer. Physicians, young and old, are often much surprised that on female subjects presenting early secondary lesions they can find no trace of the chancre. Not only does this lesion frequently undergo rapid involution, but it may also leave after it no trace after the lapse of a few days. Fournier watched a chancreous erosion run its course in fourteen days and leave after it no trace. I recall the case of a woman who had a pea-sized erosion in the cleft formed by the labium majus and the labium minus which I watched carefully and in which the chancreous lesion lasted eighteen days and disappeared without the slightest trace.

Sometimes on the involution of the chancre a reddened, very slightly hyperplastic spot is left, and one can tell that the affected tissue is slightly denser than normal. Then, again, the only trace left is a circumscribed redness, at first rather deep. This gradually pales and the mucous membrane is left apparently healthy. While in many cases the chancre is very ephemeral and leaves a trace which rapidly disappears, in other cases the red spot is very persistent and it may be seen for several months.

The chancreous erosion leaves no evidence of a cicatrix; the reason of this is that the syphilitic new growth composing it is not copious and condensed, consequently it does not destroy or impair the tissue which it infiltrates, and is absorbed without carrying away with it any normal cells. This lesion, however, is sometimes accompanied with an œdematous condition of the tissues under and around it. This complicating condition consists in a slow, aphlegmasic thickening of the tissues. It may be limited to a moderately wide area around the sore, or it may be extensive and involve much tissue. It is not at all uncommon to see the whole of a labium minus or majus the seat of this indurating œdema. Tissues thus affected present a dense and somewhat elastic structure, but the induration in its early periods is not as hard as that of a typical sclerosis.

It not infrequently happens, particularly when the chancreous erosion is seated near the integument or upon the fourchette or prepuce of the clitoris, that well-defined induration takes place under it and it becomes developed into a typical indurated chancre. This condition is sometimes strikingly well marked at the fourchette, and is well shown in Fig. 2. This presents a V-shaped chancreous erosion, with deep induration of the tissues of the parts. This chancre, when seen here, frequently presents a raw-beef appearance, which is very characteristic.

*The Scaling Papule or Tubercle.*—This lesion is found upon the outer surface of the labia majora; upon the labia

minora when they are long and their structure resembles that of the integument; upon the prepuce of the clitoris when it is long and protrudes from the vulva; upon the internal surface of the thighs, the inguinal folds, and the hypogastrium. It begins in a very insignificant manner as a small, dull-red colored papule, which may or may not be scaly. This lesion increases circumferentially, but usually does not become much elevated. As it grows it develops into a flat, brownish-red and sometimes purplish-brown, perhaps scaly, elevation of the skin, with a sharply defined margin. It may be of the size of a silver five-cent piece, or as large as a silver quarter or half dollar. Its shape is round or oval, and sometimes, owing to the conformation of the parts, it is of irregular outline. It may present well-marked induration, or this symptom may be scarcely recognized. In general this lesion is unique, and exceptionally two are found. Though it is cold and aphlegmasic in appearance, it presents to the eye a compactness of structure giving one the impression that it has come to stay. It runs an indolent course, and may last several weeks or even months. In most cases it leaves after it a deep-brown, even a purplish, stain, and not uncommonly atrophy of the skin is produced by it. When irritated, this lesion loses its epidermal covering and becomes raw and exuding. It then is developed into what is called the ecchymatous chancre (a bad term), and may be better classed as an incrustated chancre. This form of chancre is far from uncommon in women.

In rare cases the scaling papule becomes very large in area and very much elevated, so as to form what we may call an elephantine chancre. I have seen one on the buttocks of a woman the diameter of which was two inches and a half, and another on the upper portion of the thigh which had an area of an inch and a half and a height of three quarters of an inch.

In rare cases the scaling papular chancre develops around a hair, and forms a conical lesion of the color just described. When this occurs it is not uncommon to see two or three or even more of these chancres. They may run an uncomplicated course, or they may become attacked with ulceration, in which event the diagnosis is much obscured, and a lapse of time is required before their nature is rendered clear and positive. The resulting ulcers have well-defined, elevated margins and a saucer-shaped surface. They vary in size from a certain to half an inch. All chancres of this variety are irreparable in disappearing.

*Elevated Papule or Tubercle (Ulcus Elevatum).*—This chancre presents the appearance of a well-circumscribed, flat or elevated lesion, whose surface is similar to that of the chancrous erosion. Indeed, it may be defined as a chancrous erosion in which the hyperplastic process has been very active and productive of much infiltration. Cases not infrequently present themselves in which we can watch the development of the *ulcus elevatum* from the chancrous erosion.

The *ulcus elevatum* is seen upon the mucous surface of the labia majora and minora in its most typical form. It is well shown in Fig. 3, in which the two elevated excoriations are seen, one seated on each internal surface of a labium majus. This form of chancre is round, oval, or slightly

irregular in outline, and varies in size from a third of an inch to an inch and even an inch and a half. Its surface is smooth and even velvety, and its color is of a deep red, like muscular tissue. In some cases the smoothness of surface is replaced by an uneven, slightly granular condition; but in uncomplicated cases nothing like a warty or strawberry surface is seen. In old and irritated cases of the *ulcus elevatum* a slightly warty appearance of the surface may be present. In other cases, as the lesion grows old, it assumes the appearances of *condylomata lata*. The surface may be flat, slightly convex, or even decidedly concave. As a rule, the margination of the *ulcus elevatum* is not sharp and steep, but in some cases this feature is observed. The secretion of this lesion is serous in character, and is mixed with a few leucocytes. In consequence of the irritation of catarrhal or blennorrhagic secretions, as a result of uncleanness and alcoholic and sexual excesses, and of prolonged walking and fatigue, the *ulcus elevatum* may become much hypertrophied, and around it may develop a greater or lesser amount of indurating œdema; or, from the same causes, it may become more or less ulcerated, in which event its nature is often rendered very obscure. A hyperæmic condition of the parts around, due to pregnancy or any other source of irritation, is very often a complication which obscures and delays the diagnosis.

Careful palpation rarely shows very marked induration in the *ulcus elevatum*. This symptom is usually difficult of detection, and when found it is generally of the parchment-like order, or it simply gives the impression of a rather greater condensation of tissue than is normally found. When this lesion is situated near the juncture of the mucous membrane and the integument it may present marked induration. As a rule, this form of chancre is chronic in its course, lasts weeks and months and slowly resolves, leaving a deep-red spot which may be very persistent and is often very useful in diagnosis.

*The Incrustated Chancre.*—This chancre, as we have seen, is not uncommonly found upon juxtapudendal cutaneous surfaces, and indeed upon any portion of the integument. It has been stated that incrustated chancres are not found within the area of the mucous membrane of the vulva, but that their habitat is the tegumentary structures. It is true that in most instances vulvar chancres are of the erosive or papulo-tubercular variety. This is largely due to the fact that the coaptation of the parts and their moisture, aided very often by pathological secretions, cause any surface covering of the chancre to melt away and to disappear. But it is not at all uncommon to find chancres at the fourchette in an incrustated state, and I have twice seen this condition in vaginal chancres. Further, in somewhat rare cases, I have seen incrustated chancres of the clitoris, and also of the labia minora, when these structures have been prominent in the vulva and have come to look like integument.

At the fourchette, besides the raw-beef chancre—the outcome of the chancrous erosion—we not uncommonly find incrustated chancres.

This incrustation in women, as in men, forms upon an eroded surface—namely, the chancrous erosion, the indurated nodule, or the diffuse indurated plaque. It begins as

a thin, white film, presenting a glistening appearance. This film, which is formed of necrotic tissue elements and serous secretion, increases in extent and thickness until a species of false membrane is formed which is wrongly called diphtheritic membrane. As this membrane increases it becomes of a grayish-cream color, which in some instances is tinged with a very light tint of green. In this state the membrane of syphilitic chancre may be said to present its typical appearance. It may thus remain more commonly in men than in women; in general, however, we find that the grayish color in some parts (if not the whole) of a chancre becomes brownish or even blackish, probably from blood admixture or from dirt contamination. This condition is well shown in Fig. 4, which portrays a chancre of the fourchette in a pregnant woman (the vulva has a bluish-red hue).

Then again in women, as in men, the surface of the chancre may be covered with a thin, brownish-red, necrotic-looking film, which consists of the usual membrane discolored with blood, which may be scattered in little masses over the surface of the chancre, giving it a spotted appearance. This necrotic chancre is well shown in Fig. 7.

Then again we find, though very rarely, the chancre called by Fournier *chancre multicolore*, or the *chancre en coquarde*, in which the surface of the chancre presents a series of concentrated zones of different colors which are thought to resemble a cockade. In Fig. 5 this chancre is beautifully delineated, the colors being red in the center, green, then red, and then gray. This play of color is due to some peculiar changes in the typical syphilitic membrane of the chancre.

The incrustated chancre may present a smooth surface or it may be more or less uneven and undulating, owing to the nature of the parts upon which it is seated.

In Fig. 6 an incrustated chancre of the mons Veneris is well shown. It is developed among the hair, and the infiltrating neoplasm has caused little elevations around the hair follicles; consequently the surface of the chancre is quite uneven. This is the usual condition of chancres when developed upon hairy parts.

In the incrustated state the chancre may remain indolent and aphlegmasic for a long time. As the lesion becomes old it is not uncommon to find that it is complicated with a greater or less amount of indurating œdema. In Fig. 6 this complication is shown very clearly in the great hypertrophy of the right labium majus. Under proper medication, the crust disappears and healing takes place in the chancre.

*The Indurated Nodule.*—This chancre, so common in men, is very rare in women. In men the syphilitic neoplasm or nodule, as a rule, circumscribes itself in compact form into a little mass; in women this new growth tends to diffuse itself more loosely into the soft mucous tissues. Thus it is that we rarely see the indurated nodule in the female sex, except on parts where the skin and mucous membrane fuse together.

The indurated nodule is seen as a sharply circumscribed mass of indurated tissue which may be rather broad and flat, or it may have a rather narrow base, sloping edges, and flat surface. The color of the lesion is dull red, and its

surface may be smooth and glossy, or it may present the grayish color of the incrustated chancre with all the variegations found upon that. In Fig. 8 an indurated nodule is admirably well shown at the lower part of the left labium majus. This nodule, like most of its class, presented a cartilaginous hardness, sharply limited to its margin. The course of this lesion is very chronic, and on its disappearance a pigmented spot may be left or atrophied skin may be evident.

*The Diffuse Exulcerated Chancre.*—This lesion is observed not infrequently in women of the lower order who are uncleanly in their habits and given to debauches. It presumably begins as the chancreous erosion develops into the *ulcus elevatum*, and from this stage it further increases. It is usually seen involving more or less of one lip, large or small. The morbid area is much thickened, of a deep-red color, and it is exulcerated over the greater part of its surface. In these very large chancres we find a raw, uneven surface, and very often small or large ulcerating spots. Their course being very chronic and indolent, their appearance varies. At some times they are raw, like beef, and at others they look like elephantine incrustated chancres. They are very often complicated with the development of hard œdema.

As a rule, all chancres of the female genitals are unaccompanied with pain. In some cases itching and burning are complained of, and in some chancres of the clitoris and fourchette severe pain is felt.

On the labia majora we find the incrustated chancre, the chancreous erosion, the *ulcus elevatum*, the diffuse exulcerated chancre, and the indurated nodule. In the tissues of these parts indurating œdema is very often observed as a complication involving large and small portions. This complication is also found as a result of secondary lesions—such as erosions and condylomata lata.

On the labia minora the chancreous erosion, the *ulcus elevatum*, and the diffuse exulcerated chancre are commonly found. All chancres on these parts may be accompanied by mild or dense induration, which may involve part or the whole of the structure.

Chancres of the fourchette are of the erosive, incrustated, or diffusely indurated type.

Chancres of the introitus vaginae, meatus, and myrtle form caruncles are commonly ill-defined masses of induration which frequently present no characteristic appearance and whose diagnosis is usually very difficult, and frequently only possible after considerable delay and observation. On these parts it is very difficult, often impossible, to determine the extent and density of the induration.

Chancres of the vagina are very rare. Clerc never saw one, and Fournier says he never saw one seated beyond the vaginal ring. Bockhart reports a case of chancre of the middle portion of the vagina which had developed upon an excoriation produced by a tickler in ultra-libidinous coitus.

In Fig. 9 I present a very graphic picture of a chancre of the vagina in the sulcus to the right of the neck of the bladder. (In the left sulcus was a corresponding lesion.) This chancre was of the incrustated variety, and it will be seen that the false membrane is of a deep-green color, such

as we sometimes see in this form of chancre. Near the fourchette a well-marked chancreous erosion may be seen.

In the treatment of chancres in women too much attention can not be paid to the matter of cleanliness and to the production of a dry state of the parts. In some mild cases of chancre simple lotions only are necessary. When the lesion is well developed it should be constantly covered with mercurial ointment.

## DISEASES OF THE URINARY APPARATUS.

BY JOHN W. S. GOULEY, M.D.,

SURGEON TO BELLEVUE HOSPITAL.

(Continued from vol. liv, page 711.)

PART I.—PHLEGMASIC AFFECTIONS.

SECTION II.—SPECIAL CONSIDERATIONS.

### VI.

#### CYSTITIS; ITS TREATMENT.

THE treatment of sufferers from cystitis should be constitutional and local. The general indications are to remove the original cause, to relieve pain, to shorten the period of resolution of the phlegmasia, and to prevent or to combat complications. The special indications vary in accordance with the exigencies of individual cases. The prime requisite to the rational management of a particular case of cystitis is the proper interpretation of its phenomena. This is possible only after the history of the patient is known and the cause of the phlegmasia ascertained, and a close analysis is made of its subjective and objective symptoms. An accurate diagnosis can have no other foundation.

**CONSTITUTIONAL TREATMENT.**—When a subacute cystitis is traced to supersecretion of urine of low specific gravity, the cause of the polyuria is first ascertained and, if possible, removed; then the cystitis is likely to cease. For instance, when polyuria is due to temporarily disturbed innervation, the re-establishment of the nervous equilibrium is sufficient to effect the cessation of polyuria and thus to remove the cause of the cystitis. This, however, is hopeless in some cases of grave disease or injury of nervous centers, as it is in certain serious lesions of the kidneys where the polyuria is irremediable. In some cases of cystitis due to persistent polyuria, opium in moderate doses has the double effect of relieving pain and of lessening the urinary secretion. In other cases it becomes necessary to add to the opium either ergot extract or gallic acid.

In cases of cystitis caused by diminished secretion, the urine being of high specific gravity and acrid, the treatment should be such as to cause an increase in the quantity of urine. By the judicious use of mild alkaline diuretics, such as the citrate of soda or potash, largely diluted, or infusion of uva ursi, decoction of triticum repens, etc., is accomplished the indication of rendering the urine bland, and of thus causing a rapid subsidence of the cystitis.

The cases of cystitis arising indirectly from disturbance in the cutaneous circulation ordinarily get well when this

circulation is re-established, and do not require other medication than such as may render the urine bland. When, however, the cystitis persists, and vesical contracture ensues in any of the varieties of the first group, a more active treatment is necessary, as will be presently stated.

Cystitis from persistent hyperlithuria is of much more frequent occurrence than any of the varieties of this first group, and its management demands close attention. This variety of cystitis is often mis-called irritability of the bladder, and this symptom is treated with opium, belladonna, etc., and the phlegmasia is allowed to progress until permanent contracture of the bladder is established. This cystitis is as amenable to treatment and to cure in its incipiency as it is refractory to either in its advanced stages, particularly after contracture of the bladder is confirmed.

If, when the bladder is said to be irritable, the urine is examined microscopically and found to contain an excess of uric acid, and treatment for hyperlithuria is at once instituted, normal urination is soon restored and all symptoms of beginning cystitis disappear. Patients affected with cystitis due to hyperlithuria are necessarily hyperlithæmic, and this is consequent upon dyspepsia and hepatic engorgement. In such cases there is habitual costiveness, and with this headaches, muscular pains, and other symptoms of ptomainal or leucomainal toxæmia. The treatment should therefore be directed to the restoration of the digestive function and to the remedy of the consequences of its impairment. For these ends the first desideratum is free catharsis; then daily aperient medicines and the so-called hepatics, such as small doses of podophyllin, leptandrin, irisin, colocynth, and nux vomica, combined. At the same time should be prescribed alkaline waters, such as those of Vichy, from the Célestins spring, six ounces four times daily, between meals, for two weeks or, at most, three weeks. When there is a very abundant precipitate of uric acid, causing greater distress than usual, nothing seems to act so quickly as ten grains of salicylate of sodium, largely diluted, four times daily for two or three days only; as such doses are not long tolerated by the stomachs of most patients, their continuance beyond that time is not wise. This should precede the administration of the Vichy water. Five-grain or even ten-grain doses of phenacetin sometimes promptly relieve the muscular pains which so often accompany hyperlithæmia.

During this treatment and for three or four weeks thereafter the patient should abstain from eating starches and sugars, or use them very sparingly, especially at the evening meal. Abstention from all articles of food tending to cause flatulency, and from malt liquors, cider, sweet wines, etc., is essential, as they are known to be so often hurtful to the process of digestion in the cases under consideration. Sufficient bodily exercise, promotion of the cutaneous functions by frequent ablutions and frictions, and clothing suited to the state of the weather, constitute the remainder of the hygienic management.

A medication and hygienic precautions such as have just been described are likely to nip in the bud a cystitis which would otherwise become very distressing and lead to transitory, and finally to permanent, contracture with steno-

sis of the bladder. But contracture of the bladder, even of many months' standing, is not necessarily hopeless and is often cured; but this requires the greatest patience on the part of the physician and of the sufferer.

THE LOCAL TREATMENT consists in the use of medicinal and mechanical means. When acute cystitis is accompanied with transitory contracture, which is a state of rigidity of the muscular coat of the bladder preceded by frequent and painful spasmodic contractions especially at the close of each act of urination, a brisk saline cathartic should first be administered, then half a dozen leeches should be applied to the perinæum and as many to the hypogastrium. As soon as the gorged leeches drop, hot fomentations should be applied to the hypogastrium and continued for two or three days. This local depletion is of much advantage in young robust subjects, but should be omitted in those whose health has already been impaired or those who are known to be intolerant of bloodletting in any form. Two or three liberal doses of opium may be necessary to relieve the pain incident to the acute phlegmasia, and diluent drinks should be given throughout the treatment. A hot hip bath, of five minutes, every night is often very advantageous. No instrument should be introduced into the bladder except in the case of retention of urine, which, however, is of extremely rare occurrence in these cases. After a few doses of belladonna extract, a quarter of a grain four times daily for two or three days, the sensitiveness of the bladder is lessened and it allows itself to be distended by the urine rendered bland by the diluent beverages. Resolution of the phlegmasia begins and the tonic spasms of the bladder cease, so that in the course of a few more days the patient is able to retain his urine several hours, and is soon well.

In chronic cystitis with contracture, if there are not very much thickening and induration of the bladder walls consequent upon interstitial cystitis, mechanical as well as constitutional treatment is required, the indications being to remedy the phlegmasia and to restore to the bladder its normal suppleness and capacity. The constitutional treatment must be used as an indispensable adjuvant to the mechanical treatment, which would otherwise be fruitless.

The inordinate irritability of the bladder and the accompanying distressing and unduly frequent urination incident to cystitis with contracture, react upon the nervous system to the extent of seriously disturbing sleep and of rendering the patient excessively fretful. He is constantly on the alert for the moment to arrive when it is time to urinate, and ever ready to clutch any object that may serve as a fulcrum for his straining efforts. His face then becomes livid and intense suffering is thereon depicted. At the close of the act of urination he throws himself upon his bed exhausted, but not always to sleep, and even then often dreams of his distress. This scene is renewed every hour, half-hour, or even every quarter of an hour. His skin is harsh and inactive, his digestion is soon impaired, his appetite vanishes, his intestinal dejecta are hard and scanty, and he is in no slight degree under the influence of leucomainal intoxication. Such is a true picture of the worst cases. It is therefore wise to endeavor to remedy these several

morbid states before they attain this high state of development.

The first prescription should be for a cathartic. The next, for a nightly dose of twenty or thirty grains of sodium bromide, with the object of procuring sleep and of prolonging the intervals of urination. Then thrice daily five minims of tincture of the chloride of iron with a grain of quinine. Other medicinal agents that may be indicated should be used with due regard to the state of the digestive function, and not given beyond the point of tolerance. For instance, diluents should not be continued more than four days, to be replaced by balsamics, which in some cases act so favorably as modifiers of the urine; the balsamics in their turn to be discontinued in favor of some diluent. Belladonna and opium, and, for a change, hyoscyamina, not more than one two-hundredth of a grain thrice daily, are not generally well tolerated longer than four days. Such are the agents required for the constitutional treatment, but they should be used with discretion and judgment, otherwise the desired effect is not likely to be obtained.

GRADUAL HYDRAULIC DILATATION OF THE CONTRACTURED BLADDER.—The mechanical treatment consists in slow, gradual, and progressive hydraulic dilatation of the bladder, and is effected in the manner presently to be described.

An eight-ounce, pear-shaped India-rubber bag with nozzle and stop-cock is filled with a warm solution of mercuric chloride (1 to 10,000), with the addition of thirty grains of boric acid, ten minims of spirit of gaultheria, and half an ounce of glycerin. A curved gum catheter, No. 9 English scale, is introduced into the bladder and all the contained urine is allowed to flow and is measured. Suppose the quantity of urine thus drawn to be one ounce; the nozzle of the India-rubber bag is thrust into the distal end of the catheter, and, by very gently compressing the bag, as much of the fluid is slowly thrown in as the bladder can tolerate without too much pain. The fluid is then allowed to escape through the catheter and is measured. In this manner the capacity of the bladder is determined. It may be of an ounce and a half or two ounces. A second injection at the same sitting determines the degree of distensibility of the bladder, for if, after a very slight increase—two or three drachms over the amount of the first injection—the fluid drawn is tinged with blood, the operator knows that the bladder has been distended beyond its abnormally restricted dimensions, that a slight violence has been inflicted upon its mucous coat, and that he should desist from further attempts at distending the bladder during the sitting, and throw in only one ounce of fluid at a time, simply to soothe and cleanse the bladder, until the eight ounces are exhausted. On the next day, the patient being under the influence of belladonna or of hyoscyamine, the process of injection and dilatation is repeated. It may be that no gain is made over the maximum distention of the previous day, or even that there is a loss, the bladder being less tolerant than before, so that not over one ounce of fluid can be injected. This often happens during the early part of the treatment, but should not discourage the operator, for on the third day's

sitting there may be a gain sufficient to more than make up for the loss. With the exception of such retrogressions and the occasional occurrence of slight hæmorrhages, the dilatation is progressive from day to day, though the increase on some days can be measured only by the drop, while on other days it is by the drachm, but later by the ounce, and in the course of five or six weeks the bladder sometimes tolerates eight, ten, or twelve ounces of fluid. When this stage is reached the injections are repeated every second day, twice a week, and finally only once a week, until the cystitis is cured.

A very important point to which the attention of the physician should be directed is the habit that some patients, affected with cystitis and contracture, form of urinating, so to speak, by the clock. Unless this habit be soon broken, the case may well be regarded as hopeless. The example to be given is a fair illustration of this point. A patient, for the relief of whose suffering cystotomy had been proposed, said that he had also been advised to urinate often so as to keep his bladder empty as long as possible. He therefore, for several months, employed most of his time in watching a clock, and whether or not he had any desire to urinate he did so regularly every fifteen minutes. It was very difficult to convince him that he was committing a grave error, but as he was daily getting worse he finally consented to pay no further attention to the minutes by the clock or watch, and in a few days retained his urine half an hour, three quarters, and one hour, and in the course of three weeks the mechanical dilatation of the bladder was carried from two ounces to ten ounces. He was then able to retain his urine four hours. This urine, from being purulent, bloody, and offensive, became clear and normal.

For vesical irrigation and dilatation in chronic cystitis with contracture, sundry other solutions beside that already mentioned may be employed, such as of phenol, permanganate of potassium, permanganate of zinc, acetate of lead, acidulated water, etc.

It may be interesting to note some of the many different substances that have been employed for vesical injections during the past hundred years. Chopart seems to have been among the first to resort to vesical irrigations for the cure of cystitis, although the early lithotomists, among them Franco, used warm vesical irrigations as part of the after-treatment of lithotomy to cure any lingering cystitis, and although in the beginning of the eighteenth century Pierre Desault, of Bordeaux, had used, in calculous cystitis, injections of the mineral water of Barèges. Chopart at first made use of simple warm water, then of barley water, and afterward of acetate of lead dissolved in water. Later, in England and France, others used flax-seed water, soot water, tar water, calomel suspended in an emulsion of acacia gum, wine, normal urine, etc. Still later, copaiba balsam in emulsion, carbonic-acid gas, solutions of hyposulphite of sodium, bromide of potassium, iodide of potassium, tincture of iodine, corrosive chloride of mercury, chloride of sodium, carbonate of sodium, nitrate of silver, sulphate of zinc, alum, tannin, strychnine, morphine, quinine, salicylic acid, resorcin, methylaniline, peroxide of

hydrogen, divers mineral waters, etc., with varying but mostly bad results, partly because no attempt had been made to gradually dilate the contracted bladder.

It is often advantageous to change, from time to time, the formulæ of the fluids to be injected, but the essential is to bear in mind the indications of curing the phlegmasia and of restoring to the bladder its normal suppleness and capacity.

This method of gradual hydraulic dilatation of the bladder, employed by Civiale and others of his time, appears to have been soon set aside by many who have been allured by the quicker and seemingly more promising method of sudden dilatation aided by artificially induced general anæsthesia. The quick method, which does serious violence to the bladder, is generally unsafe, often dangerous, and seldom if ever successful. The slight benefit it very exceptionally confers is of short duration, and the old symptoms soon return in a more aggravated form than before. The advocacy of sudden distention of the bladder with a solution of nitrate of silver, thirty grains to the ounce, is even more unwarrantable. This rash procedure has been adopted by many who have regretted it, for when the patients have survived the violence and cauterization, their bladders have become permanently and incurably contracted, stenosed, and thickened from the consequent interstitial phlegmasia.

**NITRATE OF SILVER IN CYSTITIS.**—In obstinate cystitis nitrate of silver is unquestionably a valuable therapeutic agent when used at the right time and in solutions of suitable strength, but very strong solutions not only fail to cure but do serious mischief. After the bladder has been gradually dilated to eight or ten ounces and the same amount of urine is retained without causing pain or hæmorrhage, if this urine is still purulent, a weak solution of nitrate of silver may, with much advantage, be employed for irrigation every four or five days. A grain of crystallized nitrate of silver is dissolved in eight ounces of distilled water, then, after having drawn off all the urine contained in the bladder and washed it twice with pure water, two injections of four ounces each are rapidly made with the nitrate-of-silver solution. In four or five days the process is repeated, but the quantity of nitrate of silver is doubled. After this the solution is gradually increased in strength to three, four, eight, and sixteen grains of nitrate of silver to the eight ounces of warm water, and it is very rarely necessary to increase the strength of the solution to thirty-two grains to the eight ounces, for, after eight or ten sittings, all the good that may be expected is accomplished. Guyon, of Paris, uses the nitrate-of-silver solution by way of instillations of ten, fifteen, twenty, or thirty drops of the strength of from five to sixty grains to the ounce, once and sometimes twice daily, principally in trachelocystitis.

As far back as the latter part of the last century strong solutions of nitrate of silver were used in the treatment of cystitis, from fifteen to sixty grains to the ounce of distilled water. In some instances, instead of the silver salt, corrosive chloride of mercury was used in the same strength and, it is said, with the same effect. Long afterward Trousseau began to use, for vesical injection, the mercuric chloride,

but only at the rate of about a quarter of a grain to the ounce. Bretonneau was a strong partisan of vesical injections, and finally employed nitrate of silver in cystitis, but his solutions did not exceed a quarter of a grain to the ounce. In 1842 Mercier revived the use of strong solutions of nitrate of silver, beginning with fifteen grains and gradually increasing to sixty grains to the ounce, and this treatment was adopted by Ricord and others, and is to this day employed.

The advocates of strong solutions declare the weak solutions to be worthless because, they say, the urine decomposes the nitrate of silver, converting it into an inert chloride, and they further say that thirty minims of urine suffice to decompose a grain of nitrate of silver. When the precaution is taken of carefully washing the bladder immediately before making the injection, surely enough urine does not enter by the ureters to decompose a grain or a quarter of a grain of nitrate of silver rapidly thrown in, and it should be remembered that two injections are made in quick succession within a minute or before the sixteen minims of urine which it receives per minute can possibly act upon the silver salt. Even in the event of polyuria, if the urine entering the bladder should be increased to thirty minims or to sixty minims a minute, which would be half a minim in the one case and one minim a second in the other case, it would not be sufficient to decompose the weakest of the proposed solutions, for to inject four ounces of fluid in the bladder requires not more than ten or twelve seconds of time, the increase in the saline not being necessarily proportionate with the watery element. Besides, as a proof that the weak solutions of nitrate of silver do act upon the mucous membrane of the bladder before the salt can be decomposed by the chlorides as well as by the acid phosphates, the injections are almost invariably followed by a burning pain, which lasts from twenty to thirty minutes, and by frequent and urgent desire to urinate for two or three hours. Without there being enough urine in the bladder to decompose the nitrate of silver, the ejected solution has a milky appearance, indicating its conversion into a chloride. The action of nitrate of silver is primarily upon the epithelium. A solution of moderate strength coagulates the albumin of the superficial epithelial layer, and in so doing is decomposed into an insoluble chloride. But a very strong solution is likely to act upon all the epithelial layers, and even to penetrate more deeply and coagulate the albumin and gelatin of the fibrous layer of the mucous membrane before it is decomposed, and the irritation it causes leads to interstitial cystitis. Here, then, lies the main objection to the use of strong solutions.

The repeated application of strong solutions of nitrate of silver to mucous membranes has been demonstrated to cause induration not only of the mucous membranes themselves but of their underlying connective tissue. These membranes soon lose their elasticity, being, as it were, tanned, and often spoken of as leathery. This condition of sclerosis has been observed on a large scale in the fauces among patients that had been treated during the great craze of thirty-five years ago for cantherizing the human fauces on the most trivial complaint of "sore throat," and was com-

monly termed the nitrate-of-silver throat, from which they never recovered. A similar condition has been observed during life in the urethra, from frequent applications of strong solutions of nitrate of silver and other irritants. The bladder may recover from the effects of a single injection of a strong solution of nitrate of silver, but when the strong injections are several times repeated in accordance with the directions given by those who advocate their employment, the delicate mucous membrane of this organ must suffer much more than other mucous membranes that are not the recipients of such an irritating excrement as the urine, and whose outlets are free and broad.

CYSTOTOMY, INFRAPUBIC AND SUPRAPUBIC, has been frequently performed during the past forty years for the cure of obstinate cystitis with contracture of the muscular coat of the bladder uncomplicated by the presence of a tumor, stone, or foreign body, or by prostatic obstruction. The alleged effect of this operation is that it affords complete drainage of and rest to the bladder, and therefore cures the cystitis and contracture.

The analysis of a considerable number of reported cystotomies for chronic cystitis uncomplicated with vesical tumors, stones, or foreign bodies, shows that the relief afforded by the drainage was only temporary, and that they had failed to cure the cystitis and contracture.

It is not desirable nor is it possible to keep open the neck of the bladder more than three or four weeks. Cicatrization takes place within that period, notwithstanding the use of dilating instruments, and the natural action of the vesical neck is restored and prevents the urine from escaping involuntarily. The insertion through the external wound and the long retention of a large tube does not prevent cicatrization of the urethro-vesical wound, and this tube acts injuriously as a foreign body. There is no curative power in rest and drainage of the bladder in the case of cystitis and contracture. The temporary drainage, in the most obstinate and distressing cases, may sometimes be of advantage as preparatory and adjuvant to the hydraulic dilatation of the bladder without which no permanent cure need be expected, and this dilatation should be employed a few days after the perineal cystotomy. The fluid for irrigation is heated from 105° to 110° F., and thrown in very slowly, one, two, or three ounces at a time, until a pint is used. This process is repeated once each day until eight, ten, or twelve ounces can be injected at once, but before this is accomplished the wound will have healed.

*In the case of suprapubic cystotomy* a fistula has been kept patent for months, and in some instances for years, but without curing the cystitis or the contracture.

The prescription of long rest to the bladder in these cases does not seem rational, since it is well known that the prolonged immobilization of any part so surely leads to its permanent contracture. The muscular walls of the bladder need to be exercised in cases of cystitis with contracture which has not become permanent, and this exercise is attainable by hydraulic expansion, which gradually restores to the bladder its normal suppleness and capacity.

THE TREATMENT OF ACUTE TRACHELOCYSTITIS, due to the extension of acute urethritis, consists in recumbency, a light regimen, the administration of diluent drinks to render the urine bland, the use of belladonna and opium by mouth or rectum, of hot fomentations to the hypogastric region, and of daily warm baths. For ordinary cases this treatment suffices to induce resolution in the course of a week or ten days. Balsamics are often prescribed, but only serve to disturb digestion. Other cases attended with great pain and dysuresis require local depletion, such as may be effected by leeching the perinæum, and the substitution of cold for warm applications, the cold being applied within the rectum by way of ice suppositories. No instruments should be introduced into the urethra except in the event of retention of urine. In these severer cases it is necessary to give free doses of alkalies, such as the bicarbonate of sodium, thirty or forty grains, largely diluted, four times daily for three or four days, and to increase the doses of belladonna and opium. Though the pain and urgent and frequent urination diminish under this treatment, resolution is frequently incomplete, and the affection becomes chronic. It is in these chronic cases that Guyon's method of instillations of nitrate-of-silver solution is of the greatest service; but this will be detailed in the discussion of chronic prostatitis.

The treatment of cystitis due to injuries of the bladder will be stated in connection with the subject of traumatic affections of the urinary organs.

TREATMENT OF CALCULOUS CYSTITIS.—When cystitis is caused by the presence of a calculus or of a foreign body, it is sometimes necessary to prepare the bladder for the removal of either irritant. The bladder may be spasmodically contracted around the calculus or the foreign body to such a degree as to gravely interfere with the play of the instruments introduced for the destruction or the removal of the intruder. In such a case the preparation begins with the administration of a few free doses of belladonna and opium for two or three days. During this time the bladder is daily irrigated with a warm, soothing antiseptic solution, dilating it gradually as much as necessary for the safe destruction of the calculus or the extraction of the foreign body; either operation being successfully performed, the after-treatment consists in daily irrigations tending to cure the phlegmasia and to restore the bladder to its normal state.

IN THE MANAGEMENT OF CYSTITIS DUE TO OBSTRUCTION BY LOCAL URETHRAL STENOSIS the physician is guided by the character and caliber of the stricture, by its complications, and by the general physical state of the patient. If the stricture, though very narrow, is free from complications and susceptible of expansion, its gradual dilatation is at once begun and practiced every third or fourth day. As soon as the urethral canal is thus sufficiently enlarged at the strictured point to render urination moderately free, the acts are less painful, less frequent, the bladder is soon emptied, and the cystitis begins to subside, to be well, as a general rule, when the urethra is dilated to its normal caliber. When, however, the stricture is not dilatible beyond three or four

millimetres, it should be cut longitudinally from within, and a catheter introduced to draw off the purulent urine and to permit the thorough cleansing and disinfection of the bladder. The catheter is afterward used for every act of urination, and the bladder washed once each day until there are no more signs of cystitis. If there happens to be vesical contracture, gradual hydraulic dilatation becomes necessary. When internal urethrotomy is contra-indicated by reason of the extreme narrowness of a stricture seated in the scrotal or perineal region, especially if there be a urinary fistula or an abscess, the operation of external perineal urethrotomy should be performed without delay, to give free vent to the urine; but this urine should be drawn off by means of a large catheter passed through the wound, and the bladder thoroughly cleansed once or twice daily. If there is no serious complication toward the upper urinary organs, the cystitis is likely to be cured, or nearly so, before the external wound is fairly healed.

THE CYSTITIS OF ELDERLY MEN affected with prostatic enlargement requires unremitting attention from the earliest period of its development, because of the grave consequences that arise from neglect to relieve the bladder of the stagnant urine which so surely undergoes fermentation with the conversion of its urea into carbonate of ammonium, and the extension of the consequent phlegmasia to the whole of the vesical mucous membrane and even to its underlying fibrous coat. This cystitis is generally of slow development. At first the urine contains very little pus, only the lower fundus of the bladder being affected. The amount of residual urine may not exceed an ounce, but this residuum gradually increases until the bladder is abnormally distended. The urine is then ammoniacal, slimy, and fœtid, and urination is unduly frequent and very painful. If before the cystitis reaches this state of development the catheter is used once or twice daily and the bladder is properly cleansed, further fermentation is prevented and the phlegmasia subsides. But if the cystitis has already extended to the whole vesical mucous membrane, proper measures should be taken to check the ammoniacal conversion of the urea of the urine and to counteract its ill effects. The amount of urea metamorphosed into ammonium carbonate is not less than two per cent., or nearly ten grains to the ounce of urine. This percentage of ammonium carbonate is quite sufficient to excite cystitis, to act upon the albumin of the pus-corpuseles, and to saponify the fats of the pus, the result of these changes being the slime, mis-called ropy mucus, which is sometimes so tenacious that it can not be extracted through an ordinary catheter. There are two ways of relieving a bladder gorged with tenacious slime. One is to convert the carbonate into an acetate of ammonium by throwing in largely diluted acetic acid, thus liberating the fats and liquefying the slime, which then assumes a milky appearance; the other is to remove the slime by aspiration through a large-sized catheter.

The bladder is then to be emptied by means of an ordinary catheter five or six times every twenty-four hours and thoroughly cleansed with an antiseptic solution once and sometimes twice daily, night and morning. About ten

ounces of fluid at a temperature of 105° to 110° F. may be employed for this purpose, one third to be injected and three successive injections to be made at each sitting. The substances dissolved may be varied from time to time—boric acid with the corrosive chloride of mercury, phenol, permanganate of potassium, etc.—and continued as long as the urine is alkaline. When the urine resumes its normal acidity the injections need not be used oftener than twice a week, but the use of the catheter should not be abandoned. When the urine contains phosphates in great abundance, two grains of acetate of lead to the ounce of warm water, with two minims of acetic acid, may be used with good effect, there being a double decomposition and the formation of a soluble acetate of the bases, and of an insoluble phosphate of lead. Water acidulated with nitric or hydrochloric acid, two or three minims to the ounce, may also be used with advantage. These two means constitute the prophylaxis of phosphatic stone.

One of the gravest of the consequences of the cystitis of elderly men suffering from prostatic obstruction is contracture with diminished capacity of the bladder; this, happily, is of comparatively rare occurrence, while contracture with increased vesical capacity is the rule. These patients are tormented by constantly painful and unduly frequent urination, and, if allowed, would introduce the catheter every half-hour, for they suffer all the pangs of acute retention of urine, and their bladders bear very little if any artificial hydraulic distention. Though they are the most hopeless of all cases, their suffering is often alleviated by free doses of belladonna and opium, and by one or two daily injections of warm water rendered denser by the addition of glycerin and some salt of sodium or potassium.

The physician is sometimes called upon to minister to the suffering caused by complete retention of urine, another grave complication of the cystitis arising from stagnation of urine due to prostatic obstruction. His duty in such a case is to ascertain the degree of enlargement of the prostate and the exciting cause of the occlusion of the urethro-vesical orifice. He may learn, by patient cross-examination, that the sufferer had been exposed to inclement weather, or had committed some excess, or that his rectum had not been relieved for several days, etc. He may also learn how long since the bladder had been emptied, whether the patient or any one else had used a catheter, and if so what kind of catheter; if catheterism had been unsuccessful, how many times it had been tried; whether hæmorrhage had followed the attempts made to enter the bladder, and whether he had had any chills after the catheterisms. Then he should make a general examination of the case to ascertain the condition of the patient and the degree of distention of the bladder. If he finds the patient suffering much constitutionally from his ailment he should not at once resort to catheterism, but first administer a broth, a stimulant, and an opiate, and finally an enema to empty the rectum. In an hour or two he may select a suitable catheter, introduce it and draw off only a pint of urine, two hours after this another pint, and so on every two or three hours until the bladder is empty. The dangerous procedure of precipitately evacuating the overdistended bladder of elderly men

has already been pointed out, but an example will be given later. The best instrument for ordinary use is a No. 9 English curved gum catheter. If on account of a longitudinal rent in the prostate the point of the catheter is arrested and by gentle manipulation can not be made to enter the bladder, the instrument should be withdrawn and armed with a properly curved metal stylet and reintroduced after the manner of William Hey, which consists in carrying the instrument to the point of obstruction and in then withdrawing the stylet, at the same time pushing in the catheter seized with the left thumb and index. The suddenly increased curve changes the direction of the vesical extremity of the instrument, and the bladder is thus entered. If no urine flows it is probably because the eye of the catheter is obstructed by a clot of blood which can be driven out by injecting quickly through the instrument an ounce or two of water. It sometimes happens that this method of catheterism fails. Then the invaginated catheter of Mercier may be substituted with the fairest prospect of success. This ingenious contrivance has many times obviated the necessity for puncture of the bladder, which is to be regarded as an evil and performed for temporary relief only, in case suitable catheters can not be procured for many hours. The invaginated catheter consists of two catheters—one metallic, the other non-metallic. The first or female part is a thin-walled No. 10 English silver catheter, eleven inches long, very slightly curved, and having in its concavity, about half an inch from the point, an oval eye five eighths of an inch in length and three sixteenths in breadth. From the vesical extremity of the eye is an inclined plane, which is lost in the floor of the opening at a distance of a quarter of an inch, serving to tilt up the point of the male part. This male part is a flexible but firm "gum" catheter, No. 7 English, eighteen inches long, fitting loosely in the lumen of the female part, and having a single eye an eighth of an inch from its point. The manner of using the invaginated catheter is to introduce the male into the female part as far as the eye of the female part, then to pass the instrument as far as the obstacle and engage the point of the metallic part in the false route, and finally to project the male part, which will override the false route thus blocked and enter the bladder. The female part can then be withdrawn and the male part left in as long as may be required; this is the reason for the increased length of the male part.

In case of multiple false routes in the prostatic region and of failure of all methods of catheterism, the patient is rendered insensible by ether, or, better, by nitrous-oxide gas, and is placed in the lithotomy position. A grooved steel staff is then introduced into the urethra as far as possible, a median incision is made in the perinæum, the membranous urethra is laid open longitudinally with a bistoury, the left index finger is passed as far as the bladder to serve as a guide for a broadly grooved director; the finger is then withdrawn, and, with the guidance of the director, a deep downward cut is made with a long-bladed beaked bistoury in the median line through the base of the prostate, including the neck of the bladder. Before withdrawing the director a soft India-rubber tube of not less than ten milli-

metres in diameter is introduced and retained in position for forty-eight hours. Meanwhile the bladder is irrigated twice or thrice daily. After the withdrawal of the tube, the same, or one slightly smaller, is used once or twice daily to cleanse the bladder, though the urine may be flowing involuntarily. In the course of three or four weeks the false routes and the external wound heal by granulation, and ordinary catheterism may be employed to empty the bladder.

**VESICAL HÆMORRHAGE.**—When the overdistended bladder has been precipitately emptied and an abundant hæmorrhage has ensued, this viscus should not again be allowed to become distended, and means should be promptly taken to arrest the hæmorrhage. In such a case may be administered twenty-minim doses of fluid extract of ergot every two or three hours, or ten grains of gallic acid dissolved in glycerin, or the same quantity of quinine dissolved in dilute sulphuric acid. Vesical injections of cold water, slightly acidulated with acetic acid, may be made after each evacuating catheterism. Then it is essential that the bladder be kept empty. So long as the urine is much in excess of the effused blood, this blood retains its fluidity; but when the blood is in excess, coagulation rapidly takes place and the bladder is soon distended with dense clots which can not be extracted until they are broken up and removed by aspiration through a large catheter.

A vigorous farmer, seventy years of age, was seen in consultation at his home on the last day of June, 1891, on account of profuse vesical hæmorrhage due to his having suddenly emptied his overdistended bladder five days before when he had ridden forty miles in a light carriage. The bladder was filled with clots and distended to the level of the umbilicus. Notwithstanding the existence of prostatic obstruction, catheterism was easy, but, after a little bloody urine had escaped, a clot occluded the gum catheter. A metallic catheter, ten millimetres in diameter, was substituted and moved in different directions to break up the clots, several ounces of which were aspirated by means of Bigelow's instrument. A lithotribe was then used to further break up the clots, and these were likewise aspirated. After this several injections of diluted vinegar were made and the patient allowed to rest and sleep for three hours, when catheterism was again employed, but with a smaller instrument, which was not this time obstructed, and a pint of bloody urine drawn. After several cold irrigations with ten per cent. of vinegar the ejected fluid contained very little blood and no more clots. The hæmorrhage gradually lessened and ceased on the third day. It had lasted eight days in all. Meanwhile evacuative catheterism had been practiced every five hours. In a week the family physician wrote that the patient was in good condition, though he had been troubled with polyuria, which necessitated the more frequent use of the catheter, and that the cystitis was under control, the bladder being daily irrigated. The patient is at this date in excellent condition.

**TREATMENT OF THE CYSTITIS DUE TO DISEASE OR INJURY OF THE GREAT NERVE CENTERS.**—The discussion of the

treatment of cystitis will now be closed with some hints respecting the management of the cystitis which arises from stagnation and fermentation of urine due to disease or injury of the great nerve centers. In patients who survive grave lesions of the brain or of the spinal cord for weeks or months it has long since been observed that frequently the immediate cause of death is traceable to consecutive lesions of the urinary organs, such as cystitis, ureteritis, pyelonephritis, calculous formation, etc., all arising from stagnation of urine in the bladder, whose sensibility is blunted or even destroyed, owing to the nerve-center lesion, and that when early attention is given to the impaired urinary organs while the primary disease or injury is undergoing treatment, the life of the patient is prolonged and his suffering lessened. The needed treatment is simple and effective, so far as the urinary organs are concerned. Very soon after a patient becomes paraplegic his bladder ceases to act and rapidly fills with urine; therefore it should be artificially emptied at once, if it is not overdistended. So long as the urine is clear and of acid reaction, simple evacuative catheterism, practiced at regular intervals, suffices to prevent stagnation and cystitis. But when the urine is already turbid and alkaline the bladder should be irrigated once or twice daily with suitable solutions. This plan of treatment has been current in Bellevue Hospital for the past twenty-six years, and it is believed that the lives of many patients have thus been prolonged for months and even for years. Experienced surgeons know so well how commonly, in depressed fractures of the skull, the bladder becomes distended with urine, that the first direction they give to their aids is to empty the patient's bladder, with the object of preventing overdistention and cystitis.

(To be continued.)

#### NOTES ON OPERATIONS UPON THE MASTOID PROCESS.\*

By E. GRUENING, M. D.

At the Aural Department of the Mt. Sinai Hospital forty-seven operations of opening the mastoid process have been performed since January, 1889. This number exceeds that of any previous triennial period, the increase being due to the prevalence of influenza. The cases operated upon may be classified as follows:

*First.*—Acute caries or empyema of the mastoid, with profuse purulent discharge through the middle ear—thirty-nine cases.

*Second.*—Caries of mastoid with cortex intact, without purulent discharge through the middle ear—two cases.

*Third.*—Chronic otitis media purulenta, with presence of cholesteatomatous masses in the antrum and tympanic cavity—three cases.

*Fourth.*—Chronic otitis media purulenta, with sclerosis of mastoid process, thrombosis of lateral sinus, and pyæmia—two cases.

\* Read before the American Otological Society at its twenty-fourth annual meeting.

*Fifth.*—Chronic otitis media purulenta, with sclerosis of mastoid and abscess of brain—one case.

Of these forty-seven cases, in all the acute cases, forty-one in number, the patients recovered completely and were discharged cured; of the chronic cases, in the three complicated with a formation of cholesteatomatous masses the patients were improved, but not cured; while the remaining three admitted to the hospital with thrombosis of the lateral sinus and abscess of the brain, respectively, died.

The method of operation which I had employed in the Mt. Sinai Hospital up to 1889 was strictly that of Schwartze. Küster and von Bergmann have criticised Schwartze's method severely because the cases require a lengthy after-treatment by frequent syringing. Küster has proposed another mode of procedure in which the opening of the mastoid is systematically combined with the removal of the posterior wall of the osseous portion of the external auditory canal, and the introduction of a drainage-tube through the mastoid opening and the canal. The strictures made by these gentlemen are justifiable from a surgical, but not from an otological, standpoint. My operations demonstrate that, by an extension of Schwartze's method, the prolonged after-treatment becomes unnecessary, and the function of the ear is respected. This was particularly noticeable in the forty-one acute cases mentioned in this series.

The modification of Schwartze's method as practiced by me during the past three years consists in the systematic removal of the whole external wall of the mastoid process. I begin my operation through the soft parts with an incision extending from a point situated two centimetres above the linea temporalis and carry it to a point below the apex of the mastoid. The periosteum is then lifted from the whole extent of the mastoid process, and the tendinous attachments of the sterno-cleido-mastoid muscle are severed. The outer surface of the bone is thus completely exposed, and, if found diseased and softened, opened with a sharp spoon at the point affected. If the bone is found firm and apparently healthy, the opening is made with chisel and mallet on a level with the spina supra meatum. Thus far I follow Schwartze's directions. The next step in my operation is the removal of the whole cortex by means of the bone forceps or rongeur. I use for this purpose an instrument specially constructed with a view to the dimensions of the field of operation. Removal of the cortex brings into view a number of cavities filled with granulation tissue, for the dislodgment of which the sharp spoon is used. These small cavities are thus generally converted into one large cavity, whose bony walls may be found softened in many spots. Again the sharp spoon is used to clear away the softened and diseased bone. Now the large cavity thus made can be fully explored, and the site of the lateral sinus and its relation to the antrum determined. The importance of this localization was shown in one of my cases, where the sinus covered the path to the antrum into which I intended to penetrate. In some cases the sinus was found behind this path; in others, below that level. It is evident, then, from my experience in this series of operations, that localization of the sinus is generally possible, and thereby the subsequent step of entering the antrum rendered absolutely

safe. After the operation the cavity is packed with iodoform gauze and a bandage applied.

Of the forty-one acute cases, forty remained aseptic during the entire process of healing, which, on an average, lasted four weeks. Throughout that time neither the wound nor the ear was syringed. The packing was removed every fourth day and replaced by fresh gauze. The profuse discharge from the middle ear ceased immediately after the operation in every case. It is obvious, then, that in these cases we have not to deal with a disease of the osseous walls nor ossicles of the middle ear, but that the pus formed in the mastoid is only discharged through that channel. Furthermore, I have learned from these operations that the large incision over the mastoid may be immediately closed after the operation. This I intend to do in the future.

The fact that very extensive disease may exist in the interior of the mastoid process without the presence of any of the outward signs demanded by our text-books is shown by the two cases of central caries without apparent disease of the middle ear. Tenderness of the mastoid was the only symptom present at the time of operation. In fact, this local tenderness is the only symptom common to all cases of mastoid disease. Redness and swelling of the soft parts, local pain, headache, and high temperature may or may not be present. Tenderness, however, is a constant factor in this variety of local possibilities, and if, in spite of the employment of the ordinary means to combat it, this symptom persists, it is an indication for operative interference.

## THE CLIMATE OF BERMUDA.

BY H. E. MATTHEWS, M. D.,  
ORANGE, N. J.

THE object of this paper is to present to the profession a short study of the climate of Bermuda from a physician's point of view. This is the season when people begin to flock to Bermuda for their health; many of these return benefited, but to many others it is the worst place they could have chosen, because they lacked knowledge of the place.

The Bermudas are a group of small islands situated in lat.  $32^{\circ} 14' 45''$  N., and long.  $64^{\circ} 49' 55''$  W. They are said to number about three hundred and sixty-five, but only a few are habitable, the remainder being mere points of rock unfit for habitation. Geographically, these islands form a lagoon, being surrounded by a barrier reef containing a central inclosure of water which is subdivided by the various islands into two fine harbors. To this formation they owe their importance as a military and naval stronghold. They are of coral formation, and consist of a basis of coral limestone, with a topsoil of fine coral sand and animal and vegetable detritus.

The largest of these numerous islands is Long Island, or Great Bermuda, which is twelve miles in length and about two miles in average breadth. The capital, Hamilton, is situated on this island.

The other principal islands are St. George, on which is the town of the same name; David's Island; Ireland Island, noted for its famous dockyard; and Somerset Island.

These islands are about seven hundred miles from New York, and are reached by the steamers of the Quebec Steamship Company, sailing from Pier 47 North River, every Thursday between January 1st and May 1st, and fortnightly during the remainder of the year. The steamers are well fitted, the table is good, and the officers and men are kind and courteous to all. The agents of the line are A. E. Outerbridge & Company, 39 Broadway, New York.

Mr. Stark, in his book on Bermuda, says:

It certainly was a striking change in the scene that our voyage of sixty-five hours brought to us. We left New York at 3 P. M. on Thursday. The ground was white with snow and a raw northeast wind blowing, and on Sunday morning at sunrise we were floating on a glassy tropic sea, close to the islands. . . . Tropic, indeed, in one sense, these islands are. No frost ever visits them. The palm, banana, orange, lemon, paw-paw, India-rubber tree, with a profusion of flowers and vines, only seen in our northern greenhouses, flourish here.

The population of these isles is about sixteen thousand souls.

In a consideration of the climate of Bermuda the first point to be noticed is the temperature. The Bermudas, from their situation in mid-ocean and from the proximity of the Gulf Stream, enjoy a very uniform temperature throughout the year—the annual average being between 60° and 70° F. This compares most favorably with New York, where we habitually meet with extremes of the temperature within a few hours. It is indeed rare in Bermuda to find the temperature below 50° F. The observations of the British army, made at Prospect, give the range of temperature as follows for 1889:

CHART A.—Bermuda Temperature Chart, 1889.

MONTH.	Mean maximum shade temperature.	Mean minimum shade temperature.	Actual maximum shade temperature.		Actual minimum shade temperature.	
			Date.	Date.	Date.	Date.
January	69·6°	55·4°	74·8°	10	48·0°	30, 31
February	68·0°	53·6°	74·2°	19	47·5°	27
March	71·4°	56·1°	76·0°	16	46·8°	1
April	77·0°	61·4°	84·0°	23	57·5°	13
May	80·2°	63·0°	84·4°	1	58·0°	11
June	84·1°	65·3°	89·0°	15	61·0°	8
July	85·7°	69·6°	89·2°	4	67·0°	2, 8, 23
August	88·3°	70·5°	93·5°	28	65·0°	9
September	86·6°	71·3°	91·2°	13	65·4°	27
October	81·7°	66·7°	87·0°	2	63·8°	11
November	78·7°	64·1°	83·5°	10	59·4°	26
December	74·2°	59·3°	80·2°	21	54·2°	29

The coldest month is February, with a mean shade temperature of 60·3° F. The warmest month is August, with

CHART B.—Comparative Table of Mean Winter Temperatures.

PLACE.	NOVEMBER.			DECEMBER.			JANUARY.			FEBRUARY.			MARCH.			APRIL.

Chicago	47·2°	33·6°	38·5°	37·5°	24·7°	29·5°	32·6°	17·7°	25·8°	37·5°	23·3°	28·9°	44·3°	30·7°	34·7°	51·0°	39·7°	45·4°
Boston	49·2°	32·8°	38·2°	40·3°	23·8°	29·5°	35·3°	17·0°	26·4°	38·6°	20·1°	28·1°	43·2°	26·7°	34·2°	53·2°	36·1°	43·9°

a mean shade temperature of 79·4° F. The variations of the temperature are insignificant when compared with many of our health resorts, and to show this I have inserted tables containing the winter temperatures of several places for comparison with that of Bermuda. A glance will show the uniformity of the temperature of Bermuda.

The tables in this article are compiled from the records of the United States Signal Service and the British Army, and cover observations extending from seven to thirteen years.

CHART C.—Comparative Table of Absolute Winter Temperature—Winter meaning November, December, January, February, March, and April.

PLACE.	Yearly average.	Winter average.	ABSOLUTE MAXIMUM TEMPERATURE.		ABSOLUTE MINIMUM TEMPERATURE.		Possible winter range in degrees.
			Highest	Lowest.	Highest	Lowest.	
Bermuda	69·6°	63·9°	78·7°	73·1°	58·3°	52·2°	26·5
San Diego	60·4°	54·5°	85·6°	66·6°	47·0°	34·3°	51·3
Jacksonville	69·2°	56·5°	84·5°	76·8°	45·6°	28·8°	55·7
Nice, France	60·0°	50·8°	70·6°	.....	.....	35·5°	35·1
New York	51·2°	31·4°	71·0°	51·5°	25·0°	2·3°	68·7
Chicago	48·8°	28·0°	70·6°	50·3°	25·6°	—8·5°	79·1
Boston	48·2°	28·0°	71·9°	50·6°	18·6°	—5·0°	76·9

A careful examination of the tables will show that Bermuda enjoys a most equable temperature—even more so than San Diego. Bermuda, with its shade temperature rarely below 50° F. and never above 86° F., never hot or never cold, possesses, perhaps, a more uniform temperature than any other point on the globe.

*Humidity.*—Many authorities consider humidity of more importance than the temperature in the consideration of climate. It is certainly true that, in order to form a correct estimate of the effects of a climate upon our patients, the amount of moisture in the air must be taken into consideration, for it is well known that moist cold or moist heat is not so well borne as dry heat or dry cold. In

Table of Mean Humidity, Percentage.

PLACE.	Annual.	Nov.	Dec.	Jan.	Feb.	March.	April.
Bermuda	73·4	72·2	72·0	75·0	76·5	77·0	77·1
San Diego	72·9	66·4	67·2	71·2	74·3	75·5	72·4
Jacksonville	72·0	74·8	73·7	74·6	70·6	65·4	67·2
Nice	.....	62·4	63·0	65·9	59·9	55·7	60·4
New York	69·7	69·6	72·4	72·4	72·0	67·6	64·8
Chicago	70·8	70·8	73·9	76·0	72·5	71·5	66·5
Boston	69·6	70·5	72·7	71·8	69·6	69·4	64·8

common with most islands and sea-coast towns, the air of Bermuda contains a relatively high proportion of moisture. The situation of these islands in mid-ocean and their small

area are the causes of the high degree of humidity, for the vapors constantly rising from the encircling sea are driven over the islands by every wind that blows.

*Rainfall.*—The presence of such a high degree of moisture is considered by many to predispose to rainfall; but, perhaps, the chief cause of rain in Bermuda is the proximity of the Gulf Stream. The cold blasts rush down from the north and strike the moist humid air in the vicinity of the Gulf Stream, condensing its vapors and causing the precipitation of rain.

From the preceding remarks the inference will be that considerable rain falls in Bermuda; a glance at the accompanying table will show this to be the case:

Table of the Average Rainfall in Inches.

PLACE.	Nov.	Dec.	Jan.	Feb.	March.	April.	Annual.
Bermuda . . . . .	1.35	4.18	7.40	6.75	4.12	11.20	54.00
San Diego . . . . .	.70	2.12	1.85	2.07	.97	.68	9.49
Jacksonville . . . . .	2.95	2.89	3.28	3.45	3.13	3.55	54.68
New York . . . . .	3.34	2.97	3.50	3.23	4.07	3.25	42.52
Chicago . . . . .	2.96	2.07	2.04	2.28	2.79	3.69	37.58
Boston . . . . .	5.20	3.57	4.03	3.52	4.97	4.01	48.16

During the year 1889 there were 161 clear days, 57 overcast days, and 153 days on which rain fell. Although, as shown by the table, considerable rain falls in Bermuda, yet it is worthy of notice that a settled rain is the exception rather than the rule. The rain falls often, but in short showers or "squalls," between which will be intervals of sunshine. Moreover, from the porous nature of the soil, the rain does not lie long on the surface, but percolation and evaporation soon dispose of it. The large amount of rainfall is a factor of importance to Bermudians. There are no wells in the islands, and the inhabitants depend upon the rain-water for drinking purposes. The rain is collected in stone tanks, which are kept scrupulously clean—comparing most favorably with such contrivances in our own country.

*Wind.*—The prevailing direction of the wind is from the southwest; it also frequently blows from the northeast and southeast. The wind is usually of a gentle character and not squally, but the liability of sudden gales in southern latitudes must be borne in mind. In 1889 there were two gales.

I have made no study of the atmospheric pressure, as this, at sea-level, is of more interest to the meteorologist than to the physician.

Not among the least important points to be noticed in studying a health-resort are the accommodations, food, water, and society.

The accommodations are excellent. There are two fine, well-managed hotels—the Hamilton and the Princess—and also a number of smaller houses, where the visitor will be well housed and fed. Those who do not care for the bustle of hotel life will find many comfortable and home-like boarding-houses. The subject of water has been mentioned before.

The air is remarkable for its purity and wholesomeness. It is pure sea air, unadulterated by the dust and odors of our cities.

The roads are excellent and are unexcelled for driving

or bicycling; they wind about through nooks and crannies, every now and then running out along the seashore, and giving the traveler a glimpse of the azure-hued sea—the beauty of which defies description.

The Bermudians are a refined, hospitable, and cheerful people, and any visitor equipped with a few introductory letters may be sure of receiving every attention.

To sum up, then, the climate of Bermuda is one of very uniform and moderately warm temperature, of high humidity, and frequent rainfall. From careful inquiry and personal study, I have made the following conclusions concerning the effect of a visit to Bermuda upon patients suffering from various illnesses.

*Phthisis.*—The death-rate (total) of Bermuda is from 18 to 21 per 1,000. The death-rate from phthisis and allied tubercular complaints is about 2.5 per 1,000, and these diseases occur for the most part in the colored population. The greater proportion of deaths are due to diseases incidental to old age, these being mentioned in the government reports as "old age," "senile debility," "general debility," and other indefinite diagnoses. The general opinion concerning the climatic treatment of phthisis appears to be that these patients do not do well in low, moist climates. It is so in Bermuda; phthisis, as a rule, does not do well there; but some patients with incipient phthisis—with slight consolidation of the apex, with little or no expectoration, and with a tendency to hemorrhage—are often greatly benefited by a residence in Bermuda. But all patients with phthisis which has progressed to any extent, and more particularly those in whom the lung tissue has begun to break down, will receive more harm than benefit from a visit to Bermuda.

*Bronchitis and Asthma.*—On the other hand, cases of bronchitis and asthma, with or without cardiac complications and emphysema, do well in Bermuda, particularly if the expectoration is scanty.

Patients with pleurisy in which the effusion remains unabsorbed are very much benefited, and go on to complete recovery in Bermuda.

*Rheumatism, Gout, and Neuralgias.*—These complaints will not, as a rule, be benefited by a visit to Bermuda. These patients will do better in a climate not so humid as that of Bermuda.

*Cystitis and Nephritis.*—Patients suffering with cystitis, stone, and the various forms of nephritis, may receive considerable benefit as regards their general health. They gain flesh and strength, sleep well, and very often receive permanent relief.

Patients troubled with stomach disorders do well, as a rule; but those with intestinal disorders will do better in a colder climate.

But it is in Bermuda especially that convalescents, hypochondriacs, overworked business men, and victims of neurasthenia and mental depression, will find a haven for rest and health. They are shut off from the rest of the world, and have nothing to do but to eat, sleep, and partake of the various outdoor sports. These people, relieved of their cares, soon become cured, and to them, above all, Bermuda proves a true Bimini—a veritable fountain of health.

## FATAL HÆMORRHAGE IN AN INFANT AFTER SCARIFICATION OF THE CONJUNCTIVA.

By I. A. SHIRLEY, M. D.,  
WINCHESTER, KY.

ALICE B., mulatto, primipara, aged eighteen, was delivered September 9, 1890, of a well-developed girl baby, weighing eight pounds. Labor normal in every respect, save an occipito-posterior position of vertex presentation which naturally prolonged it. Puerperal convalescence was uneventful. Within a few days of birth the babe exhibited characteristic "snuffles," which it came by honestly, as both parents were known to be syphilitic. When about two weeks old I prescribed a weak zinc and morphine collyrium for what I supposed, from description given me, was acute conjunctivitis. After being reported better I heard nothing more of it until called a month later to prescribe for its bad sore throat, which, however, did not exist. The eyelids were closed, and I was informed were seldom opened at all, and then to a degree scarcely perceptible. The exterior of the upper lids was puffed up, resembling very much the condition frequently seen and occasionally experienced by some of us country chaps when approximating too closely our optics to the abode of the bumble-bee. On separating the lids, quite a quantity of pus was discharged and the mucous membranes were enormously swollen. Palpebral conjunctivæ were freely scarified, and sulphate of copper in substance applied. The flow of blood at this time was pretty free, but not too much, and it was directed to be let alone for a while, as a tolerably thorough evacuation was desired. This was about 9 A. M. At 12.30 P. M. the mother informed me that she believed her babe would bleed to death; I accompanied her to her home at once, and found her fears well grounded. Blood was flowing freely, terrifically from the conjunctival incisions; blood in clots, fluid blood came in a free, continuous, steady stream. The lids were thoroughly everted, and sponges, wrung out of water as hot as could be borne, forcibly applied to the bleeding surfaces; this availing nothing, ice was similarly tried, with a like result. Persulphate of iron, in powder and solution, were each in turn given a thorough trial, only to prove disappointing. The bleeding could be

plainly seen issuing from transverse incisions near the superior palpebral fold. The everted mucous membranes were approximated in such a way that a needle, curved at the point and armed with a stout silk thread, could be passed well beneath the bleeding areas, and the upper and lower conjunctivæ were firmly united by four inter-

rupted sutures in either eye. There was but little hæmorrhage from the lower lids, but it was considered best to stop every possible leak, however insignificant, and as a means to an end, and to expedite matters, the needle was made to traverse both lids and unite them. As the needle transixed, as it were, not more than a quarter of an inch of each conjunctiva, the lids remained everted after sutures were tied. Hæmorrhage was now effectually and permanently stopped. My friend Dr. McKinley, who at this time kindly saw the case with me, and I thought, from the fair condition of the heart's action, that the little one would recover, barring a recurrence of the hæmorrhage. It was given a small dose of ergot

and a stimulant, with an opiate to quiet it, and a light water dressing applied to rather hideous-looking eyes. The stimulant and ergot were to be repeated at regular intervals. I was requested, two hours later, to remove the stitches from the dead babe's eyes, who at this time showed the blanched, pale color characteristic of great loss of blood.

The query with me is, Was it of the family of bleeders? Could not the lids in persons of the non-hæmophilic type be entirely removed without fatal or even severe loss of blood? Hæmorrhage after scarification for purulent or granular conjunctivitis is not mentioned by any authority to whom I have access or been referred. Noyes, Wells, McNamara, DeWecker, Swanzy, and George Berry, while mentioning the procedure, say nothing of hæmorrhage. Dr. G. E. De Schweinitz, of Philadelphia, in a recent number of the *Medical Record*, reported a case of dangerous and alarming hæmorrhage from the application of nitrate of silver to purulent conjunctivæ in an infant of six weeks. Darnier, in the *St. Louis Medical Review*, advises deep incisions and scraping with sharp spoon in granular conjunctivitis, but says not a word about hæmorrhage. Dr. Robert Sattler, of Cincinnati, has observed persistent hæmorrhage after entropium and trichiasis operations, but not after simple scarification. Therefore, from what I have been able to glean, I believe the case to be unique, and shall henceforth keep a watchful and suspicious eye, for some hours at least, on every conjunctiva that I scarify.

## A CASE OF PTYALISM BY COLCHICUM.

By JOHN SHAND, M. D.,  
EDINBURGH, SCOTLAND.

"Colchicum occasionally acts as a diuretic and expectorant, and a case is on record of violent salivation supposed to have resulted from its use."—  
United States Dispensatory, 1887, page 886.

The following case bears out the confirmation of the conjecture expressed in the above-given quotation. This conjecture has been extremely interesting to me, as it is the only instance, in the human subject, of such a probability that I can find recorded in our large library of the College of Physicians. I say in the human subject advisedly, for there is a record in the last century of two dogs being profusely salivated by colchicum. This, as I consider it, valuable suggestion appears never to have been acted upon.

My case occurred over twenty years ago, while engaged in a very large general practice in the south of Scotland.

I was called to see a lady a little past middle life who was a patient sufferer from an acute pain in the left hypochondrium, with œdema of the ankles. The œdema soon became general dropsy and the pain continued. So acute was this pain that its increase on movement of any sort terrified her into refusing to go to bed, as she preferred resting her body on one easy chair and her feet on another. This had been the case for over two months before I saw her.

Careful examination revealed no organic lesion or affection, and, as the dropsy had become alarming, I prescribed all the usual diuretics with but partial and passing effect. I felt a crisis threatened soon, and spent a little time in industriously listening to an account of all the ailments of her past life, and I could

not but remark that there was a thread or trace of rheumatism or gouty rheumatism indicated in all. An anxious consideration and reflection decided me to treat this recognizable thread alone for a little, and I selected colchicum as my remedial agent, and resolved to use it with every care and justice alike to patient and medicine, which I have learned as an apprentice to my father to regard with a degree of veneration in cases of that character, if wisely prescribed. In addition, from my long experience of Fleming's strong tincture of aconite, I considered it best to use the tincture of colchicum seed in a similar way.

I began with one minim every eight hours, guarded by a triple multiple of aromatic spirit of ammonia (with respect to cardiac action). This went on with regularity and precision till the twelfth day, when a wonderful improvement was apparent in the dropsy, and the patient invited my attention to the contemporaneous profuse salivation.

On the sixteenth day dropsy and pain had alike totally disappeared.

I should mention that by the eighth day the pain was so relieved that she voluntarily took to bed at night, reserving her chairs for day.

In conclusion, she survived eight or nine years without any return of her old ailment, and her death seemed occasioned by a gradual decline of strength after a slight chill. She knew me three hours before her death, when I happened accidentally to be in the South and passing that way.

Since those days I have had many cases in which, though not so urgent as this, I have prescribed colchicum in the same way—beginning with one minim and going on till some physiological effect was produced, whether pain in the epigastrium, nausea, a diarrhoea, or, best of all, total alleviation of pain.

It is important to annotate that I tested the ptyalism more than once by diminishing the dose of colchicum, or increasing it, and I each time found a corresponding response.

The above-given case appears to me a good text for further treatment by colchicum in rheumatic gout, especially if accompanied with dropsy, though it need not be withheld till dropsy is ushered in.

## REPORT OF A CASE OF DIABETES MELLITUS, AND TREATMENT.

By J. PAGE BURWELL, M. D.,

WASHINGTON, D. C.

Mrs. L., widow, aged fifty-five, was in March, 1890, confined to bed, complaining of severe pains in all of her limbs and in her back. Her tongue was red and glazed, and micturition was frequent. Upon examining the urine, I found the specific gravity 1.048, and the reaction acid. A test with Fehling's solution showed a large quantity of sugar.

I prescribed three grains of gallic acid and one grain of aqueous extract of opium in capsules three times a day; also two grains of ergotine night and morning. The diet consisted of milk, beef-tea, and gluten bread. Under this treatment the sugar gradually disappeared until September, 1890, when the specific gravity was found normal, and there has not been a trace of sugar since, although I have made frequent tests. All treatment has been discontinued since November, 1890, and she has not been restricted in diet since January, 1891. She sleeps well, is free from pain, and has a very healthy appearance.

## THE NEW YORK MEDICAL JOURNAL, *A Weekly Review of Medicine.*

Published by  
D. APPLETON & Co.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JANUARY 2, 1892

### UNSUSPECTED GALL-STONES.

DR. JOSEPH M. PRICE, of Philadelphia, presented at a recent meeting of the Philadelphia County Medical Society several cases of abdominal section. His paper, with the discussion, has been published in the *Medical and Surgical Reporter* for December 12th. His most striking case was one of obstinate obstruction of the bowels the true cause of which was a large biliary calculus which was not suspected until the operation was well under way. The patient was a woman of forty-five years, having pain and some extension of the normal area of dullness over the hepatic region. There was no jaundice, fever, vomiting, or tympanites, but there was slight weakening of the heart's action. Large and frequent doses of cathartics had been given without avail. The patient's general condition was good, but a very anxious facial expression began to assert itself. The patient desired that something radical be undertaken for her relief. An abdominal section was done in the hepatic region. The incision, two inches long, almost immediately disclosed a greatly distended gall-bladder. This was tapped, and the contents proved to be a clear gelatinous fluid, without any of the characteristics of bile. The gall-bladder was examined and two large stones and one small one were removed. The direct cause of the intestinal obstruction was the pressure of this enlarged bladder, with its gall-stones, over and upon the transverse colon, the anterior abdominal wall yielding but slightly and causing all or nearly all of the effects of overdistention, as the gall-bladder gradually enlarged, to be expended on the colon, thus creating as complete an obstruction as had ever been met with by Dr. Price.

Dr. Price speculates regarding the possible outcome of the case if the operation had not been resorted to and if the patient had survived long enough for protective adhesion to take place between the gall-bladder and the bowel. The transverse colon was in contact with the gall-bladder, and was therefore favorably located for that form of "Nature's cure" which is obtained through inflammatory adhesion, ulceration, and discharge of the calculus into the adjacent or underlying intestine. In not a few such cases the adhesion does not take place at the "point of election," so to call it, and a leakage of bile into the peritoneal cavity may cause disastrous results. Or the ulcerative process may be excessive, and a defective coaptation of the organs in question may permit of an escape of the stone or stones into the peritoneal cavity. Or, again, both the adhesive and the ulcerative processes may be conducted safely and the stone be lodged in the intestine—the ileum, for example—and there cause complete obstruction and a fatal result. Two cases of this last-named accident have been observed by Dr.

James Collins, of Philadelphia, within the last ten years, and he believes that deaths from similar conditions are not infrequent.

These are the instructive points to be gleaned from the paper and discussion given in the *Reporter*. One other point, bearing upon the remedial influence of operative interference, is the proposition of Riedel, in the *Centralblatt für Chirurgie*, No. 21. He refers to those attacks of pain and digestive disturbances that depend upon old adhesions, bands, etc., on and about the gall-bladder. In thirty-six abdominal sections for diseases of the gall-bladder and gall-ducts he has found no fewer than fifteen cases of adhesion, of which nine existed between these organs and the omentum, four with the bowel, and two with the abdominal wall. These adhesions are not of necessity connected with severe inflammatory processes—far less with suppurative changes—but may have been produced by a catarrh of the gall-bladder, with or without the existence of calculi. Riedel advocates a more frequent employment of laparotomy in cases of obscure abdominal diseases, in the belief that many of them are due to bands thus surreptitiously formed, and thinks that a degree of relief out of all proportion to the apparent structural disturbances can be accomplished by discovering and breaking up these adhesions.

#### SO-CALLED "HYDRARGYRUM LACTATUM."

A CASUALTY from the misuse of drugs is reported from Bay City, Michigan. Somebody blundered, and somebody else lost his life; so says the *Western Druggist*. A physician of that town fell into the habit of prescribing "hydrargyrum lactatum," meaning thereby a preparation furnished by a Chicago dealer in drugs which is said to contain one part each of calomel and of bismuth subnitrate and eight parts of milk sugar. This did no harm so long as the prescriptions were taken to the shops where the Chicago specialty was known. But the day came when a change in pharmacists was made by the patient. The new pharmacist, ordered through his wholesale dealer a bottle of "hydrargyrum lactatum," and received a supply of Merck's "lactate of mercury." Merck's catalogue contains that item, with the price marked at \$1.00 an ounce. Chemistry recognizes "hydrargyri lactas," or mercurous lactate, and, although it is not often heard of in medicine, Watts's *Dictionary of Chemistry* describes its composition and properties. This preparation was dispensed three times before any injurious effects were noticed, but the fourth dispensing of it was followed by the death of the patient. An analysis of the drug is said to have shown the presence of mercuric lactate as well as of the mercurous salt, and it is suggested that a reduction had been going on in the bottle after it left the wholesaler's hands. If this is the fact, and can be proved, it will tend to lighten the condemnation launched by the *Western Druggist* against the conductors of the Chicago drug house for its "criminally reckless terminology," in that they adopted a harmful name to cover a comparatively mild "specialty." It will also tend to lighten the feeling of responsibility for this particular "accident" in the mind of the physician, against whom the *Druggist* alleges

that his conduct was "little less than criminal," because he prescribed a substance about which he really knew nothing. There seems to be a fatality about nearly all these "specialties, or combinations made by some known-to-us-alone process"; sooner or later, they become the occasion of loss of life, or they get everybody into trouble who has anything to do with them. The remedy of known composition is not always safe, but it comports more thoroughly with the dignity of the profession to employ it, so that even if perchance a casualty should follow its legitimate use, it will not be necessary to resort to that most idiotic of excuses, "I did not know it was loaded"—the plea of those who point pistols at their best friends and kill them!

#### MINOR PARAGRAPHS.

##### INFLUENZA AND THE BIRTH-RATE.

THE year 1890 did but little to arrest the impending depopulation of France. Four months of it were signalized in Paris by a lower birth-rate than at any period during the five preceding years. There are, on an average, a thousand children born in Paris every week, and sometimes eleven or twelve hundred. The forty-first week of 1890 told a different story. There were only seven hundred and eighty-seven births. One author considers this due in great measure to losses of men in the Franco-Prussian war, affirming that, about twenty-five years after war, pestilence, and famine, there is always a deficiency in the birth-rate, owing to the absence of children of the fallen, who would in one generation themselves become fathers. To this Dr. Roeser fails to agree, and in the *Revue générale de clinique et de thérapeutique* for December 9, 1891, gives an interesting diagram illustrating the falling off in the birth-rate, which he ascribes to the influenza that reigned in Paris from the 26th of November, 1889, to the early days of February, 1890. His observations form an interesting contribution to the statistics of epidemics and natality.

##### PILOCARPINE AS A REMEDY FOR RABIES.

IN the November number of the *Indian Medical Gazette* Assistant Surgeon Troylucko Nath Ghose gives an account of a case of supposed rabies in which recovery followed the use of eleven subcutaneous injections of pilocarpine hydrochloride, of a fifth of a grain each, in the course of seven days. The author remarks that in the course of his twenty-five years' practice he has seen probably not fewer than twenty cases of rabies, but has never before succeeded in curing one, and he adds that he has never known of a recovery from the disease in India. He was led to use the drug in this case by seeing it mentioned in Martindale's *Extra Pharmacopœia* as having effected a cure in two cases out of four. Before resorting to it, and before the spasms had come on, he excised the cicatrix that had formed as the result of the bite, and kept the sore open for two weeks, with the effect of stopping a shooting pain that had been felt in the scar.

##### THE NEW JERSEY STATE BOARD OF MEDICAL EXAMINERS.

THIS board has just reported to the Governor on the operation of the medical-practice law of 1890. It is stated that over a hundred physicians have been allowed to register in the old way, because the county clerks were unable or unwilling to discriminate between fraudulent and legal diplomas, though such registration does not entitle the person registered to practice

medicine. Of the 2,500 legalized physicians in the State, ten per cent. are registered on bogus or fraudulent diplomas. The board examined 101 candidates, issued 82 licenses to practice medicine in the State, and 3 licenses in the preliminary branches, and rejected 16 candidates. It is to be hoped that public sentiment will support the board in its efforts to protect the community from quacks and incompetent men.

#### THE MEDICAL CORPS OF THE NAVY.

The *Report of the Chief of the Bureau of Medicine and Surgery* for the year 1890, dated October 7, 1891, is a pamphlet of rather more than a hundred pages. It contains the usual tabular matter, an account of the health of the force, and interesting reports from the medical officers in charge of various stations and individual vessels. It seems that during the year 1,422 persons were on the sick list with influenza, among whom there was only one death. On the average, the men were off duty on account of this disease between five and six days, making a total of 7,719 days lost to the service.

#### MERITORIOUS SERVICES BY ARMY MEDICAL OFFICERS.

In a recent list issued by the Major-General commanding the Army, giving the names of officers and enlisted men who distinguished themselves by specially meritorious acts or conduct in service in 1890 and in the more recent Indian campaign in South Dakota, are mentioned the names of Lieutenant-Colonel Dallas Bache and Major J. Van R. Hoff, surgeons, and Captain H. P. Birmingham and Captain W. L. Kneedler, assistant surgeons.

#### ITEMS, ETC.

**The Sloane Maternity Hospital.**—It is announced that five summer courses, each lasting four weeks, will be open to physicians and advanced students. Each class is positively limited to six. The five courses will be the same, so the only choice is in regard to the time. The courses begin on May 2, June 1, July 1, August 1, and September 1, 1892. Each course offers the following advantages: I. *Twenty lessons in operative obstetrics* (five each week). Each student in turn will practice upon the phantom all the common and most of the rarer obstetric operations. Special endeavor will be made to render these exercises of the greatest practical value. II. *Attendance at all births in the hospital* (about fifty may be expected in four weeks). Clinical instruction and every facility for observation of births, normal and abnormal, will be given. III. Instruction in the treatment of puerperæ and infants. Students in turn will make rounds daily with the house staff. IV. Instruction in abdominal palpation and auscultation and vaginal touch. Examination of gravidæ will be practiced daily by each student in turn. For further information application may be made in person or by letter to Dr. E. A. Tucker, at the hospital.

**The Metropolitan Medical Society.**—This society, which meets fortnightly, is limited to a membership of eighty. Officers for the ensuing year were recently elected as follows: Dr. F. A. McGuire, president; Dr. William Cowen, vice-president; Dr. F. F. Marshall, recording secretary; Dr. Henry S. Stark, corresponding secretary; and Dr. H. N. Vineberg, treasurer.

**The Alumni Association of Mt. Sinai Hospital** held its first annual dinner at the Arena on December 7th. About thirty gentlemen were present. Dr. Alfred Meyer presided.

**The Obstetrical Society of Leipsic.**—At the four hundredth meeting of the society, held on October 19, 1891, Dr. Paul F. Mundé, of New York, was elected a corresponding fellow.

**The Death of Dr. Robert A. Kinloch, of Charleston,** took place on December 23d. He was in the sixty-sixth year of his age. He had

been the professor of surgery at the South Carolina Medical College and surgeon-in-chief of the Roper Hospital so long that he occupied without dispute the leading surgical position in his State. He was at one time president of the State Medical Society. During the late war he was medical director of the South Atlantic Division in the Confederate service.

**The Death of Dr. Simon T. Clark, of Lockport, N. Y.,** took place on Thursday, December 24, 1891. He was fifty-five years old, was born in Canton, Mass., and was graduated from the Berkshire Medical College in 1861.

**The Death of Dr. Buckminster Brown, of Boston,** occurred at Auburndale, Mass., on Thursday, December 24, 1891. He was seventy-two years old, was born in Boston, and was graduated from the Harvard Medical School in 1844.

**The Death of Sir James Risdon Bennett, M. D., F. R. S.,** is announced in the *British Medical Journal* as having taken place recently. The deceased, who was an ex-president of the Royal College of Physicians, was eighty-two years old.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 13 to December 26, 1891:*

By direction of the Acting Secretary of War, a Board of Medical Officers is constituted, to consist of—

IRWIN, BERNARD J. D., Colonel and Surgeon; ALDEN, CHARLES L., Lieutenant-Colonel and Surgeon; GIRARD, ALFRED C., Major and Surgeon; and BRADLEY, ALFRED E., First Lieutenant and Assistant Surgeon—to meet at Headquarters Department of the Missouri, Chicago, Ill., on February 1, 1892, for the examination of candidates for admission to the Medical Corps of the Army, and for such other business as the Surgeon-General may desire to bring before it. MEARNS, EDGAR A., Captain and Assistant Surgeon. By direction of the Acting Secretary of War, so much of Par. 1, S. O. 265, A. G. O., November 13, 1891, as directs him to report to the commanding officer, Fort Mackinac, Mich., is revoked; he will proceed to El Paso, Texas, and on arrival there report for duty to Lieutenant-Colonel John W. Barlow, Corps of Engineers, member of the commission appointed for the location and marking of the boundary between Mexico and the United States.

WALES, PHILIP G., First Lieutenant and Assistant Surgeon, is granted leave of absence for one month, with permission to apply for an extension of one month.

GARDNER, EDWIN F., Captain and Assistant Surgeon, is, by direction of the Secretary of War, relieved from further duty at Fort Porter, N. Y., and also from temporary duty at Fort Columbus, N. Y., to take effect upon the arrival at that post of FISHER, WALTER W. R., Captain and Assistant Surgeon, and will then proceed to Fort Mackinac, Mich., for duty.

ROBINSON, SAMUEL A., Captain and Assistant Surgeon, is granted leave of absence for twenty days, to take effect on or about January 2, 1892.

#### Society Meetings for the Coming Week:

MONDAY, *January 4th:* German Medical Society of the City of New York; New York Academy of Sciences (Section in Biology); Morrisania Medical Society (private); Brooklyn Anatomical and Surgical Society (private); Utica, N. Y., Medical Library Association; Corning, N. Y., Academy of Medicine; Boston Society for Medical Observation; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Hartford, Conn., Medical Society; Chicago Medical Society.

TUESDAY, *January 5th:* New York Obstetrical Society (private); New York Neurological Society; Elmira, N. Y., Academy of Medicine; Buffalo Medical and Surgical Association; Ogdensburg, N. Y., Medical Association; Medical Societies of the Counties of Broome (quarterly) and Niagara (semi-annual—Lockport), N. Y.; Hudson (Jersey City) and Union (quarterly), N. J., County Medical Societies (Chittenden, Vt., County Medical Society; Androscoggin, Me., County Medical Association; Baltimore Academy of Medicine.

WEDNESDAY, *January 6th*: Society of the Alumni of Bellevue Hospital; Harlem Medical Association of the City of New York; Medical Microscopical Society of Brooklyn; Medical Society of the County of Richmond (Stapleton), N. Y.; Bridgeport, Conn., Medical Association; Penobscot, Me., County Medical Society (Bangor).

THURSDAY, *January 7th*: New York Academy of Medicine; Society of Physicians of the Village of Canandaigua, N. Y.; Brooklyn Surgical Society; Boston Medico-psychological Association; Obstetrical Society of Philadelphia; United States Naval Medical Society (Washington); Washington, Vt., County Medical Society (annual—Montpelier).

FRIDAY, *January 8th*: New York Academy of Medicine (Section in Neurology); Yorkville Medical Association (private); German Medical Society of Brooklyn; Medical Society of the Town of Saugerties, N. Y.

SATURDAY, *January 9th*: Obstetrical Society of Boston (private); Worcester, Mass., North District Medical Society.

## Proceedings of Societies.

### SOUTHERN SURGICAL AND GYNÆCOLOGICAL ASSOCIATION.

*Fourth Annual Meeting, held in Richmond, Va., November 10, 11, and 12, 1891.*

The President, Dr. L. S. McMurtry, of Louisville, Ky., in the Chair.

(Concluded from vol. liv, page 723.)

**The Pedicle in Hysterectomy.**—Dr. I. S. Stone, of Washington, D. C., read a paper on this subject, in which the three principal methods were described and illustrated by colored drawings, showing the arrangement of the pedicle in the abdominal wound. The author alleged a revival of interest in the operation and said that there was need for its frequent performance. The statistics were far better now than those of ovariectomy after it had become an operation of election and was firmly planted in public favor. Particular attention was given by the author to tying off the broad ligaments and the use of the elastic ligature. Sewing the parietal peritonæum to that of the pedicle in the extraperitoneal cases was also dwelt upon. The method by ventrofixation had given good results in the author's hands and served to accomplish two important purposes—viz., a speedy convalescence and avoidance of the disagreeable sloughing which followed the use of the wire clamp. It might also be used in some cases of short pedicle where the wire might not easily be applied. The methods were compared and statistics furnished, showing that the extraperitoneal method with wire and pin gave better results than either of the others, and that ventrofixation came next and the intraperitoneal method last, with a large mortality. A method of closing the capsule over the stump was described, which the author stated would answer for either *dropping* it or sewing it into the wound—ventrofixation. In the latter case the suspensory sutures were placed and the pedicle was sewed in, and under the lower end of the abdominal incision. Great care was required in closing the capsule over the raw surface of the stump so that separation might not occur. Owing to the peculiar contractile nature of the capsule, care must be taken to leave sufficient length for approximation of the peritoneal surfaces.

The uterine arteries were to be tied in any case when hemorrhage was likely to occur and drainage might be required. Besides reference to methods, the author described the process

through which the wound passed after supravaginal hysterectomy. All myomatous tissue should be removed, which could only be effected in some cases by a process of reduction of the pedicle. This was very important, as in the operations where a large amount of myoma was left more time was required for atrophy and absorption to reduce the pedicle to its proper size. Great danger to the patient was apt to follow where a broad base of the tumor was left in either method of treatment, because this mass must be disposed of before the patient could entirely recover. The author had observed a sufficient number of cases to declare that permanent fixation of the stump to the abdominal wall was the rule where the extra-abdominal methods were used, and especially when the broad ligaments were cut away to prevent traction.

**A Plea for Progressive Surgery** was the subject of the President's address. Dr. McMurtry said that within fifteen years the entire practice of surgery had been revolutionized. New methods had been introduced and new regions invaded; comparatively recent teachings had become obsolete in practice and modern treatises had been recast. The science and art of gynecology, which a few years since had been limited to a small and narrow field, had grown into a great branch of medical science and practice. Formerly divided between midwifery and surgery, as a minor branch of one or both, gynecology had become an independent and essential department of the healing art.

When Marion Sims announced through the columns of the *British Medical Journal* that he believed the proper course of treatment in every case of gunshot wound of the abdomen was to open the stomach, search for the bleeding points and secure them, and suture intestinal perforations, he had been pronounced by many eminent surgeons to be a dreamer. The suggestion of Sims had been most timely, and shortly afterward Bull had successfully executed the operation. For years the treatment by opium in full doses had been pursued, with death in waiting. Now there was scarcely a State in the Union in which one or more patients had not been rescued from certain death by prompt resort to operative treatment. He mentioned these circumstances to illustrate and emphasize the point that surgery was advanced more by the aggressiveness of the surgeon than by timidity. In the face of desperate conditions of disease and injury, where there could be no safety whatever in delay and palliation, the only treatment worthy of consideration was the aggressive course which promised success. Under such conditions the most heroic surgery was conservative and any other course was not conservative.

**The Growth of Fibroid Tumors of the Uterus after the Menopause.**—Dr. Joseph Taber Johnson, of Washington, D. C., followed with a paper on this subject, in which he said that the object of the paper was to put on record cases and opinions in opposition to this view of this important subject and to aid in recasting our views and in modifying our practice. He had within the past five years seen at least a dozen women with large growing and troublesome fibroid tumors of the uterus who were over fifty years of age, some of them over sixty. These women had been assured by their physicians that if they could get along somehow until after the change of life their tumors would not only stop growing, but that they would lessen in size, and probably go away altogether, at least the troublesome and dangerous symptoms would disappear. They had been advised against any radical operation, and encouraged to believe that as they grew older they would get entirely well. In perhaps the majority of cases this might prove to be very good advice, but the point which the author wished to make was that, as we were now better acquainted with the history and behavior of these tumors, this was no longer safe advice to

give. We could assure any woman that her tumor might not prove to be one of the exceptional cases, and that it might not grow more rapidly even after the menopause than it had before, or that it might not pre-ent complications equally distressing or disastrous. When from forty to fifty per cent. of women subjected to supravaginal hysterectomy died from the effects of the operation this was very safe and conservative counsel to follow. The possible dangers of the tumor were not equal to the probable dangers of the operation.

The author drew the following conclusions:

1. That the "rule" stated in the text-books, that uterine fibromata ceased to grow after the menopause, had many more exceptions than was generally supposed.

2. That when they continued to grow after the menopause they pursued a more disastrous course than before.

3. They more frequently became cystic, calcareous, or had abscesses develop in them.

4. These conditions requiring operation according to well-known rules of surgery, the patients were in a less favorable condition for recovery than before the menopause.

5. If the above-given conclusions were admitted to be true, it must follow that they furnished additional indications for more frequent and earlier resort to the radical operation.

In the hands of the best operators in cases where a pedicle could be secured the mortality of supravaginal hysterectomy was rapidly approaching that of ovariectomy.

**The Surgical Treatment of Anterior Displacements of the Uterus.**—Dr. C. A. L. REED, of Cincinnati, read a paper on this subject. He said anterior displacements of the uterus, when they existed to the pathological degree, were the opprobria of gynecology. It was indeed true that many wombs leaned far forward without inducing symptoms, but it was likewise true that many of them that were thus malposed did entail symptoms, objective and subjective, that frequently baffled our resources. It was a misfortune, too, that of all the displacements to which the womb was liable, those in which the organ deviated anteriorly to the normal axis were vastly the more prevalent. Thus, in an aggregate of four hundred and ninety-four cases by Nonat, Meadows, Scanzoni, Valleix, and Hewitt, quoted by Thomas and Mundé, there were two hundred and ninety-four antelexions and one hundred and eighty retroflexions, while Mundé himself reported two hundred and ninety-four antelexions, thirty-three retroflexions, and ten lateroflexions in a total of three hundred and thirty-seven cases. As the latter authority was disposed to look upon antelexions in minor stages as a physiological (even congenital) condition, it was legitimate to infer that his statistics had been based upon observations of displacements in the pathological degree. The conclusion was forced upon us, then, that of all the displacements of the uterus, those of the anterior variety were the more frequent; while the records of practice would force us likewise to the conclusion that of all the womb displacements those of the anterior variety were less amenable to treatment than any of the others.

In the treatment the term surgical was employed in contradistinction to any method of treatment by pessaries, tamponade, or electricity. It might be premised that all surgical methods devised for the relief of these conditions should be directed, first, to the removal, when practicable, of the causes of the diseased conditions proper, and, finally, to the readjustment of the diseased organs to the normal physical forces of the pelvis.

In conclusion, the author desired the association to consider—

1. The etiological relationship of contracture of the utero-sacral ligaments to antelexion.

2. The possibility of overcoming this condition by such conservative measures as rest, pelvic depletion, and appropriate manipulations.

3. The feasibility of removing the obstructive dysmenorrhœa and the sterility usually incident to these cases by the plastic operation which he had described.

4. The inexpediency of forcible dilatation for the relief of these cases and its inability to effect a permanent cure.

**The Part the Shoulders play in producing Laceration of the Perinæum, with Suggestions for its Prevention.**—

This was the title of a paper read by Dr. W. D. HAGGARD, of Nashville, Tenn., in which he made the following suggestions:

1. The patient should occupy the left lateral decubitus, at least during the second stage of labor.

2. Overcome rigidity of the vulvar outlet by the judicious use of chloroform.

3. The presenting part of the child should be supported, and not the perinæum, during the passage of the head and shoulders.

4. Support the head by pressing it well up under the symphysis pubis by placing the right thumb in the rectum and fingers of right hand expanded over the occiput.

5. To retard the exit of the shoulders, pressure should be applied to the trunk and shoulder by placing the index and middle fingers of the left hand in the rectum with the thumb in the vagina to restrain its exit.

6. Support the head and neck by pressure well over the symphysis pubis.

**Abdominal Section in a Case of Cyst of the Mesentery.**

—Dr. JAMES A. GOGGANS, of Alexander City, Ala., read a paper with this title, in which he stated that he had been induced to write a paper on the case by the fact that cysts of the mesentery were extremely rare, and that operations for their removal were most generally fatal. He said that he had been able to find the record of one case of cyst of the mesentery removed by enucleation by Guyon. The patient had died on the seventh day after the operation. One patient had been operated upon by Sir Spencer Wells; the operator in that case had incised and drained the cyst, but the patient had died within a few weeks. Three patients had been operated upon by Péan, only one of whom had recovered. One patient had been operated upon by Watts, but he did not know the result in the case. One had been operated upon by Cortes, who had incised and drained the cyst, but the patient had died from septicæmia and hæmorrhage. One had been operated upon by Bantock, who had removed the cyst by enucleation, and the patient had recovered. The conclusion arrived at as to the origin of the cyst in that case, both by Dr. Bantock and by the pathologist who had examined the specimen, had been that it originated from some fetal structure, possibly some of the rudiments of the permanent kidney. Dr. Greig Smith had said that he knew of two cases of mesenteric cyst removed by operation by a friend, but that he could not relate them to him, as they had not yet been published. The patient upon whom the author had operated for a cyst of the mesentery was a young woman, twenty-one years of age, daughter of a physician of Columbus, Ga. She had not been well for two years, but did not know that her abdomen was becoming larger until three months before the operation. During those three months she had been treated for abdominal dropsy, and had suffered much uneasiness and pain in the abdomen, and at the time of the operation her pulse had been 120 and her temperature 100° F. The cyst had been quite large, had occupied mostly the left side of the abdomen, had extended from under the ribs into the left lumbar region, had dipped downward into the pelvis, and had extended three or four inches beyond the median line of the abdomen into the right side. He said that he had first removed about a quart of

the fluid by aspiration on February 7, 1891. The fluid had been thin and of a dark color, and had contained albumin, phosphates, and chlorides. The patient had not been benefited by the operation, and the abdominal section for the removal of the cyst had been made on February 24, 1891.

The cyst had been covered with omentum and mesentery, and loops of small intestine had been imbedded in its walls. An attempt had been made to enucleate it, but hæmorrhage had been so free that the idea of enucleation had soon been abandoned. A point as remote as possible from blood-vessels and intestines had been selected, and the cyst incised and drained. More than a gallon of a thin, dark-colored fluid had been evacuated, the sac irrigated with hot water, the lips of the incised sac stitched to the upper angle of the abdominal incision, and a glass drainage-tube introduced to the bottom of the cyst. The abdominal incision had then been closed with silkworm-gut sutures. The author was confident that the cyst had been retro-peritoneal. The time consumed in the operation had been twenty-five minutes. The sac had been irrigated three or four times in the twenty-four hours and the drainage-tube gradually withdrawn. The patient had suffered much from nausea and vomiting, which he had attributed to the close connection between the walls of the sac and the loops of small intestine. The patient had made a good recovery within thirty days. He presented a picture of the patient which was taken on November 1, 1891, which showed her to be in perfect health.

**Thinness of the Uterine Walls simulating Extra-uterine Pregnancy** was the title of a paper by Dr. GEORGE J. ENGELMANN, of St. Louis. The author said there were many difficulties in the way of a positive diagnosis of early pregnancy, even in cases surrounded by conditions less unusual, but they assumed alarming proportions when aggravated by the curious complications which might arise in individual cases, and, above all, when conditions were simulated in which delay was dangerous and operative interference seemed called for, when a decision was urgently demanded—a decision upon which a life, and perhaps two, might depend. While the auditor might criticise at his leisure and readily distinguish the conditions depicted, it was only he who was to pronounce and to act who could realize the difficulties of this entangling and so knotty a problem.

**CASE.**—A patient, thirty-two years of age, had borne three children in the six years and a half of her married life, the youngest twenty months ago, which she was still nursing, and the menstrual flow had not as yet reappeared since the birth of this child. The patient had come to his clinic for relief from a variety of discomforts from which she had been suffering more or less for the past three months. She had complained of sick headache, vomiting spells, fullness of the stomach, belching after meals, an intermittent swelling of the abdomen, a pain in the groin, appearing before such swelling, and a small tumor above the right groin, which she had first noticed three weeks ago, and, as she had stated, had then suddenly made its appearance. An examination had revealed large varicose veins over the lower limbs; a solid, round, movable tumor above the symphysis and right groin, the cervix low and large, the uterine body thickened, lying low in the pelvis, with a certain mobility independent of the superimposed tumor, an applicator entering three inches and a half slightly forward. Notwithstanding the wine-color of the pronounced cystocele and the cervix, pregnancy had seemed out of the question, and the tumor had been diagnosed as most probably a dermoid of the right ovary, hardly one connected with the uterine wall. In the course of an examination two weeks later a very different condition of affairs had been revealed. The tumor had disappeared, and a fœtus had been found in the utero-vesical space, freely movable, apparently floating about, the small parts being distinctly

felt as if underneath a wet towel both through the vagina and abdominal walls. So distinct had the small parts appeared to the examining finger that it had seemed impossible to realize that even as much as a thickness of the vaginal tissues should intervene, and the abdominal walls must certainly have been very much attenuated to disclose the fetal parts with such distinctness. The probe had shown the uterine cavity free, six inches and a half in length, still running slightly forward, but never curving forward in the direction of the previous tumor. The treatment for the supposed subinvolution had been discontinued, the patient had been warned to keep quiet and to notify the reader upon the occurrence of any abnormal symptoms. He believed the case to be one of ectopic gestation either within the broad ligament or in the abdominal cavity after tubal rupture marked by the sudden appearance of the tumor five weeks ago, yet he was not sufficiently positive to warrant the immediate resort to the knife, and it was well that he did not do so, as per-sistent treatment and repeated examinations had resulted in labor pains and the birth of a five-months fœtus in the most correct and natural manner.

**The Removal of Necrotic and Carious Bone with Hydrochloric Acid and Pepsin.**—Dr. ROBERT T. MORRIS, of New York, contributed a paper on this subject (to be published).

**The Present Status of Cerebral Surgery.**—Dr. LANDON CARTER GRAY, of New York, in a paper thus entitled, touched upon the modern aspect of intracranial surgery. The author first passed in review our present knowledge of localization of functions of the brain, stating that we were well acquainted with the functions of the motor area, of the third frontal convolution, the frontal lobe, the island of Reil, the two upper temporal convolutions, the cuneus, certain portions of the basal ganglia, the base of the brain, and the cerebellum, and that we knew nothing, or had still under discussion, the question of the localization of the centers for the sensations of touch, pain, muscular sense, temperature sense, most of the parietal lobe, and most of the temporo-sphenoidal lobe with the exception of the olfactory lobe. He stated that operations for fracture of the skull with or without hæmorrhage, for abscess, and for tumors that were removable and localizable were usually successful; those for so-called idiopathic epilepsy were utterly valueless, as were also those for epilepsy supposed to be due to genital or ovarian irritations, while those done for epilepsy due to removable and localizable lesions of the intracranial contents were usually successful so far as the lesion was concerned, although it was a grave question as to whether the epileptic habit was ever cured; the latest operation for idiocy supposed to be due to premature ossification of the fontanelles was still under discussion and consideration, the cases being too few and too recent to permit of any conclusion, while the operations for hydrocephalus and for epilepsy due to such early infantile and fœtal lesions as porencephalia, hæmorrhage, and meningitis were indefensible. He further impressed upon surgeons the great difficulty that there often was in finding a subcortical lesion of the centrum ovale that was deep-seated or small, and the fact should be borne in mind that there might be no decussation of the motor fibers from the hemispheres, so that a lesion would be found upon the same side as the paralysis.

**A Case of Induced Abortion for Relief of Nausea and Vomiting, with Remarks.**—Dr. CHRISTOPHER TOMPKINS, of Richmond Va., followed with a paper thus entitled, in which he said that on August 1, 1885, he had been called to see Mrs. J., aged twenty-four, and, as nearly as could be ascertained, three months and a half pregnant with her first child. The patient had been born in the mountainous part of Virginia; she had had an active outdoor life and had grown up to be a woman of good height and of round, full figure. On January 14, 1884,

she had been married. While in the city of New Orleans, in stepping from the platform of a car, she had sprained her ankle. This, although treated immediately by a physician of that place and subsequently in this city, had caused her great suffering. Finally, as the usual treatment proved ineffectual the part had been put in a plaster cast; she had gone about on crutches, and after many months had recovered. In the mean time she had become pregnant, and from the first had been attacked with nausea and vomiting. Mild in the beginning, it had gradually increased in gravity, until she had sent for him on August 1, 1885.

Her husband had stated that she had had fever for two weeks. The author had found her in bed and had learned that she had been there for days; her figure was not robust and her face thin and attenuated. What little she had eaten in the past ten days or two weeks had been apparently rejected, her temperature was a degree above normal, her tongue was foul, there were sordes on the teeth, and the breath was of a sour and bilious odor. The pulse was fairly good considering her condition. Even the mention of food was distressing to her, and the sound of the dinner bell, though far off from her, caused such distress that its ringing had been discontinued by the family. The bowels had throughout her pregnancy been constipated, only moving once in two or three days. Although she was continuously retching, very little or no blood had been seen in the material vomited, except on two occasions, and then not a great deal, and such as there had been was of a florid, scarlet color. No medicine had been given and no treatment taken, except the occasional use of lime water, which she had said "did no good."

The patient had not improved up to August 7th, when the author, thinking the case one of the greatest gravity and that the question of abortion could no longer be deferred, had invited Dr. J. B. McCaw and Dr. Aaron Jeffrey to meet him in the afternoon in consultation. All had agreed that abortion must be produced in order to give the patient a last chance for her life, and it had been done.

The case was reported principally because it was an unsuccessful one and because he wished to disabuse the minds of those who were not experienced in such operations of the notion, commonly entertained and often expressed, that the induction of abortion for the nausea and vomiting of pregnancy was in skillful hands an undertaking devoid of danger and necessarily attended by success. In this case he was of the opinion that death had been the result of the protracted debility and enfeebled constitution, due to her long confinement and suffering—first, from the injury to her ankle, from which she had not recovered when she had become pregnant and had been attacked by nausea and vomiting, this last continuing till her death. Under such circumstances the outlook had indeed been very unfavorable, for to the shock of the operation and to the depression incident to the use of chloroform there had been added fever and protracted prostration, both from injury to the ankle and from want of nutrition, the result of the long-existing nausea and vomiting. He had before and since operated on women for the nausea and vomiting of pregnancy, and with success, in those whose apparent condition was much worse than that described in this case, but without the history of a previous injury or disease.

The prognosis, always unfavorable, ought, when the case was so complicated, to be of the most guarded kind. The practitioner should not, however, hold his hands on this account, for the operation afforded the poor sufferer the only opportunity of relief. The author used metal dilators instead of tents and completed the operation at one sitting. He was likewise convinced that the least possible chloroform used, the better the result.

**Officers for the Ensuing Year.**—The following officers were elected: President, Dr. McFadden Gaston, of Atlanta, Ga.; first vice-president, Dr. Cornelius Kollock, of Cheraw, S. C.; second vice-president, Dr. George Ben Johnston, of Richmond, Va.; secretary, Dr. W. E. B. Davis, of Birmingham, Ala. Place of next meeting, Louisville, Ky., beginning on the second Tuesday in November, 1892. Chairman of Committee of Arrangements, Dr. L. S. McMurtry, of Louisville.

## Book Notices.

*Artificial Anæsthesia and Anæsthetics.* By DE FOREST WILLARD, M. D., Ph. D., etc. Detroit: George S. Davis, 1891. Pp. 144.

IN this little book will be found all the more essential points connected with the administration of general and local anæsthetics. Unlike many similar publications, the book before us is thoroughly practical in spirit and devoid of purely speculative discussion; so that little time need be wasted in arriving at essential facts. The chapter on local anæsthesia is particularly good, the author having had extensive opportunities of employing Dr. J. Leonard Corning's system of anæsthetization.

Several judicious recommendations on the preparation of the patient for the administration of the anæsthetic are contained in one of the earlier chapters. This is notably true of the advice concerning the preliminary use of morphine, which the author maintains should always be given with atropine, with a view to stimulating the heart and respiratory centers.

*The Neuroses of Development,* being the Morrison Lectures for 1890. By T. S. CLOUSTON, M. D., F. R. C. P. E., Physician-Superintendent, Royal Edinburgh Asylum for the Insane; Lecturer on Mental Diseases, Edinburgh University. With Illustrations. Edinburgh: Oliver and Boyd, 1891. Pp. viii-138.

DURING the period of brain growth and development there is a liability to certain failures in nervous action which result in defects and diseases that are termed by the author neuroses of development. He attempts to treat of such conditions from the developmental and relational point of view. As a study of the relationship of disease the work is unique and of great interest. It presents numerous pathological conditions of childhood and adolescence in an entirely new light, rendering the possibility of prevention greater and the treatment more rational and scientific. The book is crowded with facts, with the comments of an unusually acute observer and original thinker, and is replete, also, with that peculiar form of suggestion that is certain to inspire thought in the reader. It is a book well worthy not only of reading but of careful study.

*A Compend of Human Physiology,* arranged in the Form of Questions and Answers. Prepared and especially adapted for the Use of Medical Students. By W. J. WATKINS, M. D., Graduate of Kentucky Medical College, Louisville, Ky. Louisville: W. J. Watkins, 1891. Pp. 10-11 to 244.

THIS is one of the latest of the class of objectionable books concerning which we had a word to say in the issue of the *Journal* for March 7, 1891, in an editorial entitled Short Cuts to Knowledge. We said that the objection to such books was that they simply presented a multitude of disconnected facts to be memorized. They ignored the relationship of these facts to each

other and paid no regard to the interdependence and relationship of diseases. The book under consideration is no exception to the rule; in fact, it seems to us that in the answers less regard than usual is given to the meaning of the questions. Isolate the answers and they convey absolutely no meaning. The author, in his preface, acknowledges his obligations to his "old friend and teacher, Dr. Sam. Cochran," but he does not say that the questions contained in the book, and the arrangement of subjects, are practically those adopted by Dr. Cochran in a pamphlet containing questions only, got up by the latter for the use of his classes. As a matter of fact, the questions in the book bear so striking a similarity to those in the pamphlet that plagiarism is unavoidably suggested. This statement is made after a comparison of the book with the pamphlet. The book may "fill a want," but it is the want of those who prefer the short cut to the "strait and narrow road."

#### BOOKS, ETC., RECEIVED.

On the Simulation of Hysteria by Organic Disease of the Nervous System. By Thomas Buzzard, M. D. Lond., Fellow of the Royal College of Physicians in London, etc. London: J. & A. Churchill, 1891. Pp. vii-113.

The Physician as a Business Man; or, how to obtain the Best Practical Results in the Practice of Medicine. By J. J. Taylor, M. D. Philadelphia: The Medical World, 1891. Pp. 4-5 to 143.

Transactions of the Ophthalmological Section of the American Medical Association, at the Forty-second Meeting, held at Washington, D. C., May 5-8, 1891.

Proceedings of the New York Pathological Society for the Year 1891.

Special Report on the Cause and Prevention of Swine Plague. Results of Experiments conducted under the Direction of Dr. D. E. Salmon, Chief of the Bureau of Animal Industry. By Theobald Smith, Ph. B., M. D. Published by authority of the Secretary of Agriculture. Washington: Government Printing Office, 1891.

The Physicians' Visiting List for 1892. Philadelphia: P. Blakiston, Son, & Co., 1892.

The Voice and its Treatment. By Arthur G. Hobbs, M. D. [Reprinted from the *Journal of Laryngology and Rhinology*.]

Intubation of the Larynx. By Carl H. von Klein, M. D. [Reprinted from the *Cleveland Medical Gazette*.]

The Arrangement of the Supracerebral Veins in Man, as bearing on Hill's Theory of a Developmental Rotation of the Brain. By William Browning, M. D., Brooklyn, N. Y. [Reprinted from the *Journal of Nervous and Mental Disease*.]

The Bilateral Pareses and Pseudoplegias of Childhood, with Special Reference to a Type of Malarial Origin. By William Browning, M. D. [Reprinted from the *American Journal of the Medical Sciences*.]

Is a Child Viable at Six and a Half Months? By Llewellyn Eliot, M. D., Washington, D. C. [Reprinted from the *Virginia Medical Monthly*.]

A Combined Laparotomy and Gynæcological Operating Table. By George M. Edebohrs, M. D., New York. [Reprinted from the *Medical Record*.]

Pathological Conditions of the Ethmoid Bone resulting from Dental Lesion. By I. P. Wilson, D. D. S., Burlington, Iowa. (Read before the Iowa State Dental Society.)

Trop de mutilations inutiles, pas assez de gynécologie conservatrice. Par le Docteur A. Doléris. [Extrait des *Nouvelles archives d'obstétrique et de gynécologie*.]

A B C of the Swedish System of Educational Gymnastics. A Practical Hand-book for School Teachers and the Home. By Hartvig Nissen, Instructor of Physical Training in the Public Schools of Boston, Mass. With Seventy-seven Illustrations. Philadelphia and London: F. A. Davis, 1891. Pp. vii-107.

Massage and the Original Swedish Movements: their Application to Various Diseases of the Body. Lectures before the Training School for Nurses connected with the Hospital of the University of Pennsylvania, German Hospital, Woman's Hospital, Philadelphia Lying-in-

Charity Hospital, and the Kensington Hospital for Women, Philadelphia. By Kurre W. Ostrom, from the Royal University of Upsala, Sweden. Second Edition, enlarged. With Eighty-seven Illustrations. Philadelphia: P. Blakiston, Son, & Co., 1891. Pp. viii-9 to 143.

Age of the Domestic Animals: being a Complete Treatise on the Dentition of the Horse, Ox, Sheep, Hog, and Dog, and on the Various other Means of determining the Age of these Animals. By Rush Shippen Huidekoper, M. D., Veterinary (Alfort, France); Professor of Sanitary Science and Veterinary Jurisprudence, American Veterinary College, New York, etc. Illustrated with Two Hundred Engravings. Philadelphia and London: F. A. Davis, 1891. Pp. viii-217.

Lessons in the Diagnosis and Treatment of Eye Diseases. By Casey A. Wood, C. M., M. D., formerly Clinical Assistant, Royal London Ophthalmic Hospital (Moorfields), etc. With numerous Woodcuts. Detroit: George S. Davis, 1891. [The Physicians' Library.]

A Volumetric Study of the Red and White Corpuscles of the Human Blood in Health and Disease, by the Aid of the Hæmatokrit. By Judson Daland, M. D. [Reprinted from the *University Medical Magazine*.]

Studies from the Pathological Laboratory of the College of Physicians and Surgeons, Columbia College, New York. For the Collegiate Year 1890-'91.

The Twenty-seventh Annual Report of the S. R. Smith Infirmary, for the Year ending May 31, 1891.

Étude sur l'exalgine d'après des observations prises à l'hôpital Lariboisière. Par M. le Dr. Émile Désiré.

## Reports on the Progress of Medicine.

### GENERAL MEDICINE.

By JOHN WINTERS BRANNAN, M. D.

**The Significance of Cheyne-Stokes Respiration as a Symptom in Cardiac Disease.**—Dr. M. A. Boyd contributes an interesting study of the phenomena of Cheyne-Stokes respiration to the *Dublin Journal of Medical Science* for July. Hayden has said, in his work on *Diseases of the Heart and Aorta*, that there is no change in the pulse or cardiac rhythm during the ascending, descending, and apnoeal periods of the respiratory act. Boyd believes this statement to be an error, and cites illustrative cases to support his opinion. The phases of the respiratory phenomenon, as he has observed them, are as follows:

1. An apnoeal period characterized by deep sleep, lividity of face, quick pulse, feeble contractions of the heart, and perfect rest from all agitation, mental and bodily.
2. An inspiratory period, with rousing of all the patient's faculties, extreme restlessness, slowing and strengthening of the pulse, apparently stronger contractions of the heart, less lividity of the face, and then a final deep inspiration.
3. An expiratory period, with inspirations gradually getting shorter and expirations longer, pulse getting quicker and heart feebleness in its contractions till expirations cease, the chest is empty, and restlessness gives place to sleep, which continues through the apnoea following.

The cardiac conditions necessary for the production of this form of breathing are, according to his experience, not alone dilatation of the aorta, but also dilatation of the right ventricle, with beginning degeneration or weakness of its walls, also hypertrophy of the left ventricle with or without dilatation, but with degeneration of its muscle or its dynamic contractile power enfeebled from any cause whereby it is unable to empty its contents into a dilated and inelastic aorta. He admits that this condition of the heart is often met with in many cases of valvular disease accompanied by atheroma of the arteries, and only produces dyspnoea. But the difference, he holds, is only one of degree. Any attack of cardiac dyspnoea produced by such alterations in the heart and aorta may become Cheyne-Stokes dyspnoea when any additional strain is put on it, so as to still further enfeeble its action and cause interference with the supply of arterialized blood to the respira-

tory center. The affection is, in fact, cardiac dyspnoea plus poisoning, or starvation of the respiratory center. Poisoning of this center or interference with its blood supply may, of course, occur without cardiac disease, and give rise to Cheyne-Stokes respiration. Apoplexy, meningitis, and uræmic coma may be mentioned as conditions in which the phenomenon has been observed. Its occurrence, however, is undoubtedly favored by the changes in the heart substance described above by the author.

**The Etiology of Diabetes.**—The Etiology of Diabetes is the title of an article by Dr. Schmitz in the *Berliner klinische Wochenschrift* for July 6th. He has had the unusual opportunity of observing 2,500 cases of the disease during his long residence at the German resort, Neuenahr.

He makes a distinction between idiopathic diabetes and mellituria or mellitæmia occurring as a complication of other affections. Of his cases, 2,115 were instances of true diabetes.

It is his opinion that the development of idiopathic diabetes is always dependent upon the presence of a diabetic predisposition.

Men are oftener affected than women; of his patients, 1,206 were male and 909 female. Idiopathic diabetes occurs very rarely in childhood, seldom in youth, but after the age of twenty increases steadily with each decade.

It is rare among the inhabitants of certain regions—as, for instance, Westphalia, the Rhine provinces, and Bavaria. On the other hand, according to Cantani, it is as common among the people of Malta and South Italy as tuberculosis is in Germany. It is frequently observed in Sweden, and a strikingly large number of cases is found among the Jews. Cantani attributes the frequency of the disease in Malta and Italy to the excessive consumption of sugar by the inhabitants of those countries. In opposition to this view, Schmitz refers to the fact that diabetes is not often met with in the populations of East Germany and of the United States in spite of their free use of sugar.

This diabetic tendency, which must be assumed to exist in certain nations and races, is usually congenital, often, also, directly inherited. In 998 cases, or almost one half of his patients, Schmitz was able to establish that near relatives had suffered from diabetes. In one family twelve cases had occurred. In 428 cases hereditary psychological disturbances were noted. Insanity, especially melancholia, was observed in the families of 263 patients.

Diabetes occurs also quite often in individuals affected with the gouty or tubercular diathesis.

Schmitz admits that an excessive consumption of sugar undoubtedly is injurious to diabetics, and that the amount of sugar in the urine varies directly with the amount eaten. In 641 of his cases the occurrence of the diabetes was preceded by a free use of sugar extending over a considerable period of time. But he insists that in each case the diabetic tendency must have been present, otherwise the disease would not have developed. He lived for several years in the United States and was struck by the very large amount of sweets eaten by the inhabitants of this country. And yet diabetes is not often observed here, though dyspepsia is a common ailment. Schmitz concludes from this fact that the Americans must be free from any tendency to the disease.

Grief, violent emotions, and nervous shocks are usually accepted as important factors in the causation of diabetes. The experience of the author leads him to oppose this view. He believes that in many of the cases in which the origin of the disease is attributed to such causes the diabetes has existed long before the shock to the nervous system has taken place.

On the other hand, he does not doubt that diabetes can be communicated from one individual to another. In seven different instances he has observed the disease in man and wife. He gives also the names of several other German physicians who have written him of similar observations on their part.

The ætiology of diabetes bears, in his opinion, a considerable resemblance to that of tuberculosis. In both affections a predisposition, usually congenital and inherited, is a necessary condition for the development of the disease. Carrying the comparison further, he suggests that perhaps diabetes, like tuberculosis, may be due to micro-organisms.

Schmitz, as we have said, distinguishes between idiopathic diabetes and mellitæmia or symptomatic diabetes. This distinction applies, however, only to the pathogenesis of the two affections. The latter disease, when of long standing, exerts the same injurious effect upon the body and calls forth the same symptoms as idiopathic diabetes. Of his cases of mellitæmia 155 occurred as a complication of the uric-acid diathesis. This form of gouty mellitæmia has usually a good prognosis. Many cases recover after a sojourn at Calsbad, Neuenahr, or Vichy, the cure being due to the influence of the alkaline waters upon the primary affection. In 128 other cases there was pronounced polysarcia.

Mellitæmia was also observed in the course of the following diseases: Cancer, general tuberculosis, valvular disease of the heart, cerebral syphilis, morphinomaniac, disease of the spinal cord, cirrhosis of the liver, amyloid disease of the liver, and Addison's disease. It also occurred six times after a fall on the head, four times after a blow upon it, once after a violent cerebral concussion in a railroad accident, and three times during convalescence from typhus fever.

Schmitz is convinced that disease of the pancreas is a cause of mellitæmia, but he has never been able to diagnose this condition with certainty.

**Intestinal Perforation in Typhoid Fever.**—Intestinal perforation in typhoid fever was the subject of a lecture recently delivered by Professor Potain and published in the *Gazette des hôpitaux* for June 9th. This accident, he says, is one of the most serious complications of typhoid fever. The possibility of its occurrence should make us always very reserved in our prognosis in this disease, as it may happen in cases which are apparently of the mildest character. He refers, in illustration, to a case which had just been under observation in the wards of the Charity Hospital. It was that of a young woman, twenty-five years of age, of strong frame and robust appearance. She had never had any illness with the exception of a recent attack of scarlet fever. She was in the third week of her convalescence from this disease when she was suddenly taken with a violent chill, with severe headache, and pain in the left side. The headache persisted, and four days later she had several attacks of epistaxis. On the following day she entered the hospital. The diagnosis remained in doubt for several days, because of the absence of positive signs. The temperature was 100.9° F., the facies was normal without lethargy, the abdomen was relaxed, with no tenderness, and there was no diarrhoea. She coughed slightly, but there was no expectoration. The only pulmonary sign was a slight diminution of resonance and vesicular murmur at the left apex. Five days after her entrance into the hospital she complained of pain and tenderness in the right iliac fossa. Her temperature began to rise, and the next day rose-spots were observed on the abdomen. The slight pulmonary signs disappeared in the mean time. The diagnosis of typhoid fever was scarcely made when all the symptoms suddenly grew much more marked. This was on the thirteenth day of the disease. The patient had a severe chill, and the pain in the right iliac fossa became intense. There was repeated vomiting and the temperature curve became very irregular and some blood was observed in the stools. Six days later the patient died in collapse.

At the autopsy, in addition to the signs of a purulent peritonitis, a large mass of fecal matter was found in the right iliac fossa. On examining the bowel, a linear perforation, two inches long, was found about two inches above the ileo-cæcal valve. Only six Peyer's patches were affected, but the ulceration was very deep. The whole thickness of the intestine was destroyed down to the serous coat. The bottom of the ulcers was smooth, composed simply of the peritoneum, in place of being ragged and uneven, as is usual in ulcerations of slow development. The gangrenous process had taken place *en bloc*, instead of gradually, involving one follicle after another. The other organs do not call for special mention.

In seeking the cause of the profound alterations of Peyer's patches and the early occurrence of the perforation in this apparently mild case of typhoid fever, Potain is inclined to attribute it to the preceding scarlet fever. He refers to the injurious influence exerted on the vitality of the tissues by scarlet fever, and the frequency with which it is followed by suppuration. It is rare to see scarlet fever thus followed

by typhoid fever, but one other case was reported by Rilliet and Barthez, in which very deep ulceration was also observed on the eighth day of the enteric disease.

Potain believes that in both cases the scarlet fever had favored the destructive process.

Intestinal perforation is observed in about two per cent. of all cases of typhoid fever, the proportion varying from one per cent. in women to three per cent. in men.

The seat of the perforation is usually at the lower end of the ileum, but it may be found in the large intestine and even in the rectum. The form may be rounded or linear; it is rarely larger than the head of a pin.

There may be certain premonitory symptoms. Profuse diarrhoea, intestinal hæmorrhage, or excessive tenderness in the iliac fossa should all put us on our guard against it.

Sometimes sudden constipation, following diarrhoea, is the first indication of the lesion of the peritonæum.

The most usual time for its occurrence is from the third to the fifth week. It is more apt to be delayed than to occur early. It has even taken place when the patient was apparently convalescent. Deep pressure in the iliac region has occasionally caused the accident. An error in diet is a more frequent cause.

The symptoms of the perforation itself are usually very abrupt. Pain, chill, vomiting, coldness of the extremities, announce only too surely peritonitis. Sometimes, however, it is of insidious development; in such cases marked variations of temperature are of diagnostic value.

Death is unfortunately the usual termination, occurring sometimes in a few hours, more frequently at the end of two or three days. A few cases of recovery have been observed. In these favorable cases inflammatory adhesions form, limiting the fecal effusion and preventing its escape into the peritonæum.

As to treatment, opium is of most service. Wet cups are useful in relieving the pain. Surgical intervention gives but little hope in this form of peritonitis. The perforation would be difficult to find and more difficult to suture, because of the lesions of the adjacent tissues. Resection of the intestine would be no less difficult, as Peyer's patches are often affected over a very extensive area.

**The Use of Drugs in the Treatment of Early Phthisis.**—Dr. J. C. Thorowgood read a paper with this title at the last annual meeting of the British Medical Association. It is published in full in the *British Medical Journal* for October 17th.

Dr. Thorowgood says that the discovery of the tubercle bacillus and the way in which it appears to be associated with the progress of the more serious forms of tuberculous disease has tended to cast drug treatment rather into the background. But in hospital practice, especially among out-patients, one is forced to do the most one can with drugs. The patients are poor and hard-worked, and can not obtain the advantages of change of air and rest. Among them phthisis is often brought about in the first instance by some neglected inflammatory mischief, such as bronchitis, pleurisy, and sometimes pneumonia. In such cases drug treatment appears to advantage. That peculiar catarrhal state of the apex which has been described as pulmonary cachexia and which is close on the borders of tubercle, and is due to a degenerated condition of the epithelium from constant respiration of bad air, improves rapidly when the patient is removed to a pure air. Where, however, we can not give the patient the advantage of removal, we have to do our best with drugs. The author lays special stress upon the good results that may be obtained in such cases from the use of the hypophosphites. Hospital out-patients who come with cough and expectoration, perhaps blood-stained at times, and who present râles at the lung apex, improve in a surprising way on taking five grains of hypophosphite of soda three times a day. The remedy may be given in plain water or infusion of calumba. In cases of persistent consolidation of lung after pneumonia, the effused products are rapidly absorbed under this treatment; and this, too, in cases in which ordinary treatment has been followed to no purpose for some time. In cases of pleurisy with effusion, the hypophosphites seem to have no effect whatever. But, when the pleura appears to have been roughened by deposits so that friction sounds of loud and coarse character

are very audible, the author has seen all these sounds vanish and the patient do well under the hypophosphite of sodium.

Dr. Thorowgood believes that a process of fatty change and liquefaction of effused product is set up and absorption follows. Sometimes the process seems to be for a time attended with some increase in temperature, and when this is the case it is well to reduce the dose of the drug or give it at longer intervals. In recurring hæmoptysis, too, the hypophosphite must be used with care. The most active in liquefacient power is the hypophosphite of potassium. The calcium hypophosphite often acts remarkably well in cases in which secretion is profuse. It checks excessive sweating and also diarrhoea.

Occasionally, but very rarely, when the hypophosphite fails to remove an apex catarrh or inflammatory deposit, something may be gained by changing to such medicines as tartrate of antimony in very small doses, or iodide of potassium, or some form of mercury.

Dr. Thorowgood passes rapidly over such drugs as the mineral acids, creasote, and guaiacol, though he has found them useful as tonics in some cases. He has much to say in favor of the inhaling respirator. He recommends its use with iodoform in ether, alcohol, or eucalyptus oil. This is soothing and excites no cough. Next to this comes the best German creasote, with or without ethylic alcohol. Thymol, carbolic acid, and iodine are all inferior to these. The patient should, after clearing his lungs as much as possible in the morning by cough, wear the perforated zinc respirator and keep it on for an hour; again in the middle of the day, and a short time at night.

Next to these inhalations Dr. Thorowgood places persistent and even severe counter-irritation. He has seen a remarkable arrest by croton liniment of phthisis of an active kind in a young woman. He thinks that linimentum terebinthinæ is also deserving of a high place, especially in chronic disease of the base of the lung.

**Acute General Miliary Tuberculosis without Fever.**—Dr. J. Joseph, of Professor Fürbringer's clinic, discusses this subject in the *Deutsche medicinsche Wochenschrift* for July 9th. It is universally agreed, he says, that the diagnosis of acute general miliary tuberculosis is often extremely difficult, and even impossible in some cases. The widespread belief that the disease never occurs without fever is responsible for many errors in diagnosis. He therefore considers it of interest to report three cases of undoubted acute general miliary tuberculosis, which ran their course entirely without fever. Two of the cases were under observation for the period of seventeen days, so that the absence of fever was evidently not simply a temporary condition.

The diagnosis in all three cases was somewhat uncertain because of the apyrexia, but the autopsy showed in each case numerous gray miliary tubercles in the lungs, liver, spleen, and kidneys.

The brain and meninges were unaffected.

Dr. Joseph adds that these cases furnish fresh testimony to the fact that acute general miliary tuberculosis may occur without any elevation of temperature whatever. The absence of fever, therefore, is no ground for rejecting the diagnosis in doubtful cases when the other symptoms point to this disease.

Dr. O. Leichtenstern, commenting upon Dr. Joseph's paper, writes in the same journal for August 6th that he has often observed cases of afebrile and even subfebrile acute general miliary tuberculosis. He thinks that it is generally recognized that there is an afebrile form of the disease. He finds it especially frequent in old people. The symptoms often resemble those of cardiac degeneration with general dropsy, or in other cases they suggest marasmus or diffuse capillary bronchitis or pulmonary œdema. He also relates the histories of two children who died with progressive general emaciation, and in whose cases the diagnosis wavered between pædiatrophy, rachitis, and enteritis. The disease ran its course in both cases entirely without fever, and to his surprise he found post mortem an acute general miliary tuberculosis, with cheesy degeneration of the lymph glands.

He has also occasionally seen the disease begin with all the typical symptoms of croupous pneumonia, such as sudden onset with chill, acute lobar infiltration, pneumonic sputum, etc. Such cases are to be explained by assuming a simultaneous development of pneumonia and the acute tubercular process.

**The Ætiology of Nephritis.**—In our report of May 2d we referred to the researches of Dr. Agnes Blum on this subject, based on the

study of two hundred and seventy cases of Bright's disease. Dr. Bluhm denied the importance of cold as a factor in the causation of nephritis, and showed that the disease of the kidney was due in almost every case to some form of infectious disease.

Dr. Viguerot (*Arch. gén. de méd.*, October, 1891) has investigated the same question, and agrees entirely with the views given above. He believes that cold acting upon a kidney already diseased may give a new impulse to the pre-existing affection and render acute symptoms which up to that time had remained latent, just as it may excite an acute pulmonary process in an individual suffering from tuberculosis.

Those persons who live in unwholesome and damp lodgings and whose skin is defective in its action, and those whose occupation exposes them to abrupt changes from a warm to a cold atmosphere, are probably predisposed to renal affections, but unless there is previous structural alteration of the kidney, even prolonged cold can not cause the lesions of chronic nephritis.

It is often very difficult to ascertain the past history of a patient. He may have had an infectious disease at some time, but he is not likely to remember the symptoms, still less to know the condition of his urine. He may since have enjoyed a long period of apparent health, his symptoms not being such as to attract his attention or to interrupt his work. When he afterward enters the hospital with the signs of acute nephritis, the renal affection is called primary, or nephritis *a frigore*.

Dr. Viguerot's conclusions are based upon his own extensive pathological and clinical observations and also upon the opinions expressed by other writers. He has seen the alterations caused in the renal tissue by the micro-organisms pass away without leaving any trace, but he has also seen them pass into the chronic state in consequence of the fatty degeneration of the epithelial elements and of the proliferation of the connective tissue.

Among the infectious diseases in question, scarlet fever holds the first place. Then follow variola and measles, also typhoid fever and diphtheria. Pneumonia, erysipelas, rheumatism, infectious amygdalitis, cholera, and septicæmia have all been mentioned by various writers as giving rise to persistent albuminuria. The author has seen chronic nephritis follow mumps in one case. Tuberculosis, syphilis, and malarial fever have also been added to the list of maladies capable of causing permanent lesions in the kidneys. In some cases the change into a chronic affection is progressive and continuous; in others it occurs after an alternation of improvement and relapse, so that one might easily be deceived and diagnosticate a primary nephritis, when in reality the process was secondary to a series of intermittent exacerbations.

Sometimes cold is not alone the exciting cause, but there is some intercurrent malady which stimulates the renal affection and helps to render it chronic. As an illustration of this, Dr. Viguerot cites a case of diphtheria with intense and prolonged albuminuria which subsequently came under treatment for typhoid fever with marked renal symptoms. It is evident in this case that the lesions in the kidneys caused by the diphtheria and which were still in process of evolution were accentuated under the influence of the typhoid fever and favored in their tendency to become chronic.

**The Local Treatment of Chronic Rheumatic Arthritis.**—Dr. A. Symons Eccles describes in the *Practitioner* for August the measures which he has found most useful in the local treatment of chronic rheumatic arthritis. He employs the term rheumatic arthritis in its widest sense to include all affections of the joints which present the clinical features of pain, swelling, and impairment of function, unaccompanied by redness and increased temperature, and in which no signs of suppuration or advanced destruction of tissue can be discovered.

Most cases of chronic arthritis afford evidence of inflammatory deposits in the fibrous and muscular tissues in connection with the joint, so that after one attack of rheumatism the fibro-serous tissues are peculiarly liable to a recurrence of inflammation should they be exposed to a repetition of the predisposing and exciting causes. Given a case of chronic rheumatism, the indications are to relieve pain, to hasten the removal of inflammatory products in and about the joint, and thus to restore it to use, while at the same time muscular atrophy is to be arrested or cured. Meanwhile constitutional remedies, dietetic and medicinal, must be employed.

Dr. Eccles's local treatment consists of a combination of massage, galvanism, and active and passive exercises. In severe cases, in which there is much pain and thickening in and around the joint, with atrophy of muscles, massage is best employed for a few minutes several times daily; centripetal friction gradually increasing in firmness, and subsequently combined with kneading of the proximal muscles connected with the joint, being applied at first as far from the forms of mischief as possible, the lightest friction of the whole limb alone being permissible at the beginning of treatment. Cautiously the firmness and near approach of manipulation to the joint may be increased, till the joint itself is, in the course of a few days, submitted to thorough manipulation, having for its object the dispersion and mechanical moving onward of the accumulated waste products, the improvement of circulation, and the stimulation of lymphatic resorption.

At the same time a stable galvanic current is applied to the joint itself, two electrodes of known dimensions being placed on opposite sides of the articulation. A current of from ten to fifteen milliampères is used for ten to twenty minutes daily by voltaic alternation.

Dr. Eccles believes that the efficacy of the treatment by the stable constant current depends upon the density of the current, and he has found the present form of electrodes in use to be the best for the different joints affected.

In the case of the finger joints he applies the current in a different manner, placing one electrode over the joint and the other in the palm of the hand, the same density being employed as in the larger articulations. Massage of the parts over which the electrodes are to be placed, when practiced directly before the employment of galvanism, reduces very considerably the resistance to the passage of the current. This is evidently the result of increasing the volume of fluid in the skin and subjacent structures. A striking proof of the therapeutic value of the treatment is the gradually diminishing resistance opposed by the diseased joint to the passage of the current from time to time as the absorption and removal of waste and inflammatory products proceed.

In the earlier days of treatment, while as yet the patient can not bear vigorous manipulation, the labile application of the ascending current to the muscles of the limb is attended by diminution of pain and stiffness.

The passive exercise of the joint is gently practiced as early as possible, care being taken not to produce too much suffering. One or two movements at each visit, gradually increasing the range of attempted motion, till finally the patient is told to aid and independently to perform the exercises most suitable to the particular condition of the joint, will slowly but surely overcome the tendency to muscular spasm, which is almost always produced by the initial movements; and, finally, after a period varying with the severity of the case, there will follow the return of power to use the limb and move the joint without pain.

**The Elimination of Toxic Products in Typhoid Fever according to the Different Methods of Treatment.**—Dr. Roque and Dr. Weill publish in the September number of the *Revue de médecine* an interesting experimental study of the above subject. They show that in typhoid fever abandoned to itself the toxins produced in the body are eliminated in part during the continuance of the disease. The urotoxic coefficient is double that of the normal; but this elimination is incomplete, so that it continues during convalescence, during which the hypertoxic quality of the urine exists for four or five weeks after the cessation of the fever.

In typhoid fever treated by cold baths the elimination of toxic products is enormous during the illness. The urotoxic coefficient becomes five or six times greater than in the normal condition. This hypertoxicity diminishes as the general symptoms decline and the temperature falls, so that with the establishment of convalescence the elimination of the toxins is ended and the coefficient descends to normal.

The cold bath is therefore an eliminative treatment; it has no specific action, inasmuch as it does not at all prevent the formation of the toxins, but it assures their expulsion as fast as they are produced.

On the other hand, when the fever is treated by antipyrine the elimination of the toxic products ceases entirely during the malady so long as the remedy is used—the coefficient descends sometimes even

below the normal. But during convalescence the discharge of the toxins takes place *en masse* for the space of five or six days. Antipyrine is therefore not an antiseptic. It does not prevent the formation of the toxic substances, but does prevent their elimination in the urine.

The authors add that since the completion of their experiments Professor Teissier has reported some observations on the effect of naphthol in the treatment of typhoid fever. His conclusions are that naphthol is a real antiseptic in this disease, inasmuch as it prevents the formation of toxic matters both during the course of the fever and during convalescence.

**The Therapeutics of the Senile Heart.**—Dr. George W. Balfour contributes an interesting and instructive paper on this subject to the June number of the *Edinburgh Medical Journal*. Senile diseases are always degenerative and tend to precipitate the natural termination of life. In them the object of treatment is not quite the same as it is in the diseases of earlier life; we no longer hope for complete restoration, but we expect to be able to remove suffering and to check decadency, and, so far as the heart is concerned, we are often successful in attaining both of these objects.

Simple irritability, says Balfour, is the earliest indication of what he calls advancing senility in the heart. The patient complains of uneasiness in the cardiac region, sometimes amounting to actual pain. Along with this there may be fits of palpitation, in the form of rapid but not usually forcible action, which come on after exertion—such as running up stairs, upon any excitement or sudden emotion, or during the night from reflex causes, mostly of gastric origin; or there may be fits of *tremor cordis* coming on suddenly, without warning and apparently without cause. The pulse is occasionally irregular in force and frequency, or it may simply intermit at regular or irregular intervals. These phenomena are always indicative of cardiac debility, which, left to itself, sooner or later leads to dilatation of the heart as well as to the other serious symptoms which we find associated with senile degeneration of that organ. These symptoms depend upon structural alterations in the heart itself, in its vascular and nervous connections, as well as in the nutritive fluid, the blood. There is no regular sequence of events in any case. Not infrequently it may terminate in a fatal attack of angina of the ordinary form, or occasionally in that form of cardiac failure which may be called *angina sine dolore*. Other patients may suffer for years from irregularity or intermission of the pulse or fluttering—*tremor cordis*—without any apparent detriment. But, in Dr. Balfour's experience, such cases, unless remedied by treatment, always ultimately develop serious cardiac symptoms, though this may be delayed even to extreme old age.

The senile heart is a term which comprehends many symptoms and a variety of signs, but which is at bottom a cardiac failure based upon malnutrition. It is therefore most important to determine the cause of this failure and to ascertain the source of the malnutrition upon which it depends. In examining such a case with a view to treatment, the pulse is one of those factors which require careful consideration. When the blood-pressure is low we must inquire into any drains upon the system and see that these are remedied; we must inquire into the amount and nature of the work done, and the exercise usually taken. Exercise is a useful tonic for a muscle, including the heart, yet with all muscles rest is often the best recuperative, and with a failing heart this is often markedly the case. The need for exercise and the capacity for taking it safely and with advantage is often a point to be carefully considered before a decision is arrived at.

The question of diet is even more important than that of exercise. In patients with weak hearts and feeble circulations the digestion is slow and the intervals between meals should not be less than five hours. As little fluid as possible should be taken with the meals, and no solid food of any kind between them. The most important meal should be in the middle of the day. The quantity of food should be restricted, but the patient may choose pretty freely as to the kind and the method of preparation.

Dr. Balfour never advises alcohol in any form for such cases. Tobacco also must be used in great moderation or given up altogether.

The drugs useful in the senile heart are few in number, but of extreme value. Digitalis is the chief and the most thoroughly reliable

cardiac tonic. It acts by improving the elasticity of the heart muscle and restoring its tone. If the dose of digitalis is moderate, this increase of tone, accompanied by an improvement in nutrition, may be kept up and continued indefinitely for months or years without fear of its action going farther. Ten minims of the tincture once or twice a day is sufficient.

Strychnine is a very valuable remedy. In many cases its continuous use is sufficient of itself to promote a cure. Arsenic is extremely useful at times, especially in cases of angina.

Next to strengthening the heart and improving the blood, lowering the blood-pressure is the most important object of our treatment. All the nitrites are available for relieving spasm and lowering blood-pressure, but nitroglycerin seems to act most rapidly and effectively. When the high intra-arterial blood-pressure is more persistent and more distinctly gouty in its character, the iodide of potassium is to be preferred, as its action, though less rapid, is more permanent. Two or three grains may be given every eight or twelve hours, and its use continued for some time. A mild course of anti-arthritis treatment is often of much service, and for this purpose there is no better drug than colchicum. The bowels should be kept moving regularly. In case of flatulence the compound galbanum pill often gives relief.

**Salicylate of Sodium in the Treatment of Pleurisy with Effusion.**—Dr. Charles Talamon calls attention (*La Médecine moderne*, June 18th) to the prompt and efficient action of salicylate of sodium in the treatment of pleurisy with serous effusion. He gives the histories of five cases, in all of which the administration of the drug was followed by the rapid absorption of the fluid. In three of the cases thoracentesis had already been twice performed, but the liquid had accumulated as abundantly as before. Salicylate of sodium was then given, and at the end of a week the effusion had entirely disappeared. A marked diminution of the fluid was appreciable as early as the second or third day of the treatment.

In discussing the mode of action of the salicylate, Talamon is not inclined to agree with Stiller, who believes that it acts simply as a diuretic. It is true that in two of his cases the amount of urine was increased rapidly from two to four and six pints a day. But, as he observes, diuresis can be provoked by other drugs, and yet the pleural effusion remains unaffected. Besides, in the three other cases the absorption of the fluid was affected just as rapidly, though there was no polyuria.

The author thinks that the experiments of Rosenbach and Pohl have a very important bearing on this question. They have proved that the salicylates, when introduced into the digestive tract, are to be found later in all the serous cavities of the body, those that are normal as well as those in a morbid condition. Hence they even advise the direct injection of the drug into the pleural cavity after the evacuation of the liquid by aspiration. The salicylate would then have a direct action upon the inflamed pleura and the remaining exudation.

Whatever its mode of action, Talamon holds that the therapeutic value of salicylate of sodium in these cases is undoubted. It should be given for a week, the dose being fifteen grains four to six times a day. The more recent the pleurisy, the more prompt the action of the drug. But it is of service at any time during the course of the disease and is especially indicated after thoracentesis, to complete the absorption of the fluid and prevent its re-accumulation.

## Miscellany.

**The Action of Tuberculin upon the Experimental Eye Tuberculosis of the Rabbit.**—The following abstract of a report from the Institute for Infectious Diseases, in Berlin, by Professor W. Doenitz, is from the *Deutsche medicinische Wochenschrift* for November 19th: Contrary to the negative results of Baumgarten, the author said, in his report before the Society of Charité Physicians, that he was now in a position to demonstrate healed tubercular processes accomplished with tuberculin, which had before been considered impossible. The author

then demonstrated in the eyes of a number of rabbits tubercular processes established by inoculation, both with pure cultures and with tubercular tissues in various stages from that of the first irritative reaction occurring about the middle of the third week after inoculation to that of the complete cure, the latter resulting in from three to four months, *the eye retaining its function as a visual organ.*

In the early part of the treatment with tuberculin the tubercular process was hastened, cloudiness of the cornea and pannus developing rapidly, whereas in the eye in the test animal the process was slower, with, however, early necrotic processes at the seat of puncture and perforation, this necrosis not occurring when tuberculin in gradually increasing doses was administered. It was immaterial whether the treatment was begun immediately after inoculation or at a time when true tubercle had been formed. The administration of the product obtained from Koel's tuberculin by Klebs was attended with only temporary improvement; the eyes were eventually lost. The same dose of the unmodified tuberculin, continued without increase, failed to produce good results. The conclusions were:

1. Tuberculin is a sure curative agent for the experimental tuberculosis of the eye of the rabbit.
2. Tuberculin shows its curative effect only after true tubercle can be demonstrated.
3. The first effect of tuberculin is a transient but severe irritation of the eye.
4. Under the continuous action of tuberculin, all irritation in the eye subsides.
5. When, before the beginning of the treatment, deep-reaching destructive processes have not occurred, the cure results in retention of the visual functions of the eye; otherwise, atrophy results.
6. To a cure, it is necessary that the tuberculin be given in increasing doses, and the continued maintenance of a not too slight reaction is essential.

**The Ohio Medical Colleges.**—Pursuant to call issued by the Cincinnati College of Medicine and Surgery for a delegated convention of the medical colleges of the State of Ohio, to be held at Columbus on December 3, 1891, representatives of the following faculties were present, viz.: Starling Medical College, Toledo Medical College, Pulte Medical College, Columbus Medical College, Medical Department of the National Normal University, College of Physicians and Surgeons of Columbus, Woman's Medical College of Cincinnati, and Cincinnati College of Medicine and Surgery. On motion, Dr. Starling Loving was elected chairman and Dr. Charles A. L. Reed secretary. On motion of Dr. C. E. Walton, representatives of the Physio-Medical Society of Ohio were admitted to a vote in the convention.

Dr. Charles A. L. Reed presented the following:

*Resolved,* By the medical colleges of Ohio, in convention assembled, that the Legislature be and is hereby requested to enact a law which shall embody the following features, viz.:

1. The creation of a board or boards of medical examiners in the composition of which equitable and just representation shall be accorded to the various recognized denominations of medical practice.
2. The examination of all candidates for the practice of medicine holding diplomas hereafter issued by medical colleges which shall be deemed in good standing by the board.
3. Exemptions from examination to extend only to those who at the time of the enactment of this law shall be recognized as legal practitioners within the meaning of existing statutes; but all legal practitioners shall be required to register.
4. A penal clause which shall secure the enforcement of the foregoing provisions.

Dr. C. E. Walton, on behalf of the Legislative Committee of Cincinnati, presented the registration law approved and promulgated by that committee. On motion by Dr. Shockey, the resolutions presented by Dr. Reed were approved. On motion by Dr. Kinsman, the secretary was directed to forward transcripts of these proceedings to each local medical society in Ohio, and to the medical press. On motion by Dr. Scoville a committee was appointed to confer with the Legislative Committee of Cincinnati for the purpose of securing such changes in the bill proposed by that committee as to make it conform to the resolutions

adopted by this convention. The chair appointed as such committee Dr. S. S. Scoville, Dr. T. C. Hoover, Dr. G. W. Mayhugh, and Dr. Charles A. L. Reed.

**An Army Medical Board** will be in session in Chicago, Ill., during February, 1892, for the examination of candidates for appointment in the Medical Corps of the United States Army, to fill existing vacancies. Persons desiring to present themselves for examination by the board will make application to the Secretary of War, before January 15, 1892, for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from whence they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates, based on personal knowledge, from at least two physicians of repute, as to professional standing, character, and moral habits. The candidate must be between twenty-one and twenty-eight years of age, and a graduate from a regular medical college, evidence of which, his diploma, must be submitted to the board. Further information regarding the examinations may be obtained by addressing the Surgeon-General, United States Army, Washington, D. C.

**To Contributors and Correspondents.**—*The attention of all who purport favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

Original Communications.

THE NATURE AND CAUSE OF  
THE SCLEROSES OF THE SPINAL CORD.\*

By CHARLES L. DANA, M. D.,  
VISITING PHYSICIAN TO BELLEVUE HOSPITAL.

THE subject of the pathology of the chronic fibroid processes of the nervous system is so large a one that I propose to limit myself to a consideration of only certain points of it. I shall take up only the fibroid processes as they affect the spinal cord, and I shall furthermore discuss the question of pathology, dwelling only incidentally upon etiology or therapeutics. I shall further exclude chronic meningitis and arterial sclerosis, because, so far as the nervous system is concerned, there is nothing in these different from similar processes occurring elsewhere.

The chronic fibroid processes of the spinal-cord substance are known as scleroses, those of the nerves as degenerative (or parenchymatous) and interstitial neuritis.

The spinal scleroses are easily divided into four classes:

I. The *primary degenerations*, in which the sclerosis is preceded by a destruction and atrophy of the nerve fibers and cells.

II. The *secondary degenerations*, in which the sclerosis is preceded and due to a cutting off of certain nerve strands from their trophic centers.

III. The *inflammatory and reparative scleroses*, in which the process is the result of a destruction of nerve tissue by inflammation, injury, pressure, or obliteration of vessels.

IV. The *mixed forms*.

Of these three forms of sclerosis it is the first about which the most obscurity prevails, and it is about these forms that the greatest interest centers. These primary scleroses are:

1. Locomotor ataxia.
2. Lateral sclerosis (if it exists).
3. The combined scleroses.
4. Multiple sclerosis.
5. Progressive muscular atrophy and its modified type, anytrophic lateral sclerosis.†

*The Nature and Cause of the Primary Scleroses.*—Modern ideas regarding these scleroses have undergone considerable change. It has been and still is taught by some that the process is a parenchymatous inflammation with secondary growth of connective tissue. But such an idea is no longer held by the majority of neurologists and pathologists. The modern conception of inflammation, that it is a process dealing with connective tissue and blood-vessels only, renders the idea of an inflammation of parenchymatous tissue and specialized cells quite untenable. The term parenchymatous inflammation is likely to be dropped from our nomenclature therefore.

If not an inflammation, what is the process?

\* Read in the discussion on Chronic Fibroid Processes before the Congress of American Physicians and Surgeons, September 24, 1891.

† Ependymal and annular scleroses are mentioned by some authors, but they belong to class iii.

So far as the microscope shows us, it is gradual decay and death of the nerve fiber and cell. In some fibroid processes, like locomotor ataxia, this decay is accompanied with the development of irritating products, leucomaines, or toxalbumins, which may produce so active a change in the connective tissue as to lead to something resembling a secondary or reactive inflammation. This is never of high grade, however, and in some forms of tabes is very slight.

In progressive muscular atrophy the decay and death produce few irritating products, though enough perhaps to account for the fibrillary twitchings and occasional hypertonic condition of the muscles.

The ultimate cause of these degenerative processes is not known. This is just now the opprobrium of neuropathology and the problem that most needs working out. They are not due to any known "diathesis."

*The Toxine Theory.*—The progressive character of the diseases like locomotor ataxia and progressive muscular atrophy would lead one to think that there is a poison constantly present in the body and constantly acting on the diseased tissue. How otherwise can we explain why an inflammatory process in nervous tissue tends on the whole to repair, to limit itself, and to recover, while a degenerative process steadily and often speedily tends to progress?

So far all bacteriological examinations have failed to discover any microbe, but the fact that many degenerative processes follow infectious fevers or syphilis has led to the suggestion that pathogenic germs have poured into the system a poison, or have so modified the cellular nutrition that there is a poison constantly thrown out which irritates and destroys certain areas of nerve tissue.

*The Senility Theory.*—Another view which may be held is that, by the presence of the poisons of certain infectious organisms, the nerve cell is stunned and its growth stunted. Its nutritional equilibrium is destroyed, and premature senility and death are brought about. Just as a man in the full tide of life is made prematurely old by a severe illness or shock, and begins to go down hill at the age of forty instead of at a later age, so the nerve cell and fiber are made unequal to their task and slowly die.

This explanation is undoubtedly the true one for the hereditary scleroses like Friedreich's ataxia. In this disease certain strands in the spinal cord were never endowed with vitality enough to carry on their functions for more than a decade or two.

The theory of a steadily secreted poison, which may be called the toxine theory, is the more hopeful one.

It is interesting in connection therewith to note that degenerative diseases do not follow those infections which do not confer long immunity—such as diphtheria, sepsis, erysipelas, tuberculosis; while diseases that do confer long immunity—like typhoid fever, measles, scarlatina, small-pox, syphilis, etc.—are most likely to set up degenerative changes. Now, as immunity is secured through the modification of cell nutrition and through the continued presence of some antitoxine in the liquor sanguinis,\* it seems not

\* J. Burdon Sanderson, Croonian Lectures on the Progress of Discoveries in Relation to Infectious Diseases. *Brit. Med. Jour.*, 1891.

unlikely that the very thing which protects against recurrence of infection may be the cause of some internal degenerative change.

The theory, however, of a premature and artificial senility is, I am rather sorry to believe, more plausible, for it is supported by the fact that in certain cases primary degenerations are started by poisons, like lead or ergot, and continue after the lead and ergot have been eliminated from the system. Also by the fact that an inflammatory process may set up a degenerative one, as when a chronic poliomyelitis develops into a progressive muscular atrophy.

Neuroglia, not fibroid tissue. These scleroses differ somewhat in the arrangement and relative amount of cells and fibrillæ. In true neoplasmic gliosis, or tumor formation, the cell predominates, but in the ordinary sclerosis a fibrillary network forms the most of the morbid structure.

Neuroglia sclerosis does not occur in the peripheral nerves, except the optic, since they possess no neuroglia matrix.

In April, 1890, Déjérine and Latulle announced (*Bull. de biol.*, March 8, 1890; *La méd. moderne*, April 17, 1890) that the sclerosis in Friedreich's ataxia was in reality a gliosis, and in this respect differed from the ordinary scleroses.

Finally, Chaslin reviews the subject again (*Arch. de méd. expér.*, 1891, No. 3) and reasserts his views as to the dominance of the neuroglia change in the primary scleroses and in certain degenerative diseases, like idiopathic epilepsy.

The validity of the revolutionary views thus put forward by French pathologists depends a good deal on the Malassez stain. I have carefully used this on cords from two cases of tabes and on several other cords with primary and secondary degenerations, and it does not give me satisfaction.

Nor, as I am informed, is Malassez himself satisfied with it. Nevertheless, the conclusions based on its use accord with probabilities, and even with the ordinary and older descriptions of general pathologists, that those chronic fibroid processes affecting the nervous system of primary origin, at least, are largely gliomatous. And we may yet have to speak of a posterior spinal fibrogliosis and multiple fibrogliosis rather than of sclerosis.

The views here suggested that the scleroses are really glioses may have some value in therapeutics. It is at least somewhat curious that arsenic and silver, which have a distinct value in the treatment of these conditions, have no value in fibroid processes elsewhere and are known to affect epiplastic tissue rather than mesoblastic.

II. *Regarding the secondary degenerations* and the chronic fibroid processes that are produced thereby, no facts of very great or general interest have been brought out in recent years. I refer more particularly to their pathology and aetiology.

Honnén has brought evidence to show that the process affects first the axis cylinder in its whole length; this swells and undergoes granular decomposition. The myeline sheath is affected later (*Contribut. expér. à la path. et à l'anat. path. de la moelle épinière*).

The view that secondary degenerations are due to a cutting off of the fiber from its trophic cell is no longer doubted.

III. *As to the inflammatory changes that lead to sclerosis*, I believe that much misconception still exists and that before a great many years there will be a reconstruction of the views concerning what is now often called chronic myelitis, transverse myelitis, compression myelitis, etc.

I take it that the neurologist can accept some such classification of inflammations as is given by the general pathologist—*e. g.*, that of Senn :

FIG. 1.

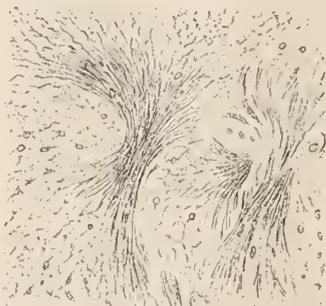

FIG. 2.

NEUROGLIA SCLEROSIS.—FIG. 1. Gray matter of the brain cortex in epilepsy. FIG. 2. The same, much magnified. (Chaslin.)

*Is So-called Sclerosis a Gliosis?*—A further point of great interest is the nature of the sclerosis in the primary degenerative processes. It has until lately been held that the sclerosis of locomotor ataxia, lateral sclerosis, etc., was composed of connective tissue. Some facts have been brought forward of late which threaten to revolutionize this view completely.

It must be remembered that, while the matrix and supporting structure of all other organs is connective tissue, the matrix of the nervous centers is partly connective tissue and partly neuroglia tissue. This neuroglia tissue, it is admitted now, is of epiplastic origin, and allied more to nervous than connective tissue. There is, to be sure, a connective-tissue membrane, the pia mater, surrounding the nervous mass, and sending sæpta into it and following the blood-vessels. But the neuroglia much more thoroughly and completely surrounds and imbeds the fibers and cells.

In 1889 Chaslin (*Journal des connaissances méd.*), studying the brains of five epileptics, found a microscopical increase in the neuroglial tissue. This, which would have been called before a diffuse sclerosis, he believes is rather a diffuse gliosis. He bases his view on a histo-chemical process suggested by Malassez. The sections are placed for ten minutes in a forty-per-cent. solution of caustic potash, then washed, stained in carmin, placed in crystallized acetic acid, washed, and mounted in acid glycerin. The connective tissue is softened and partly dissolved, and does not take up the carmine stain, while the glia tissue is not injured and is stained.

Achard and Guinon (*Arch. de méd. expér.*, 1889, p. 701), and Achard alone (*Bull. de la Sociét. anat.*, 1890, p. 200), found a similar neuroglia proliferation in multiple sclerosis, compression myelitis, tabes—in fine, in all the spinal scleroses, which they assert are in the main composed of neu-

I. The simple and plastic inflammations.

II. The infective inflammations.

Then, as the simple and plastic inflammations are mainly reparative processes, and not inflammations, we may be obliged, as Senn states, to admit some day that all true primary inflammations of the cord are due to an infective process.

This being the case, we should find few cases of either acute or chronic myelitis of primary origin, and, as a matter of fact, this is the case. Thus, in my opinion, *chronic myelitis*, so called, is really the result, as a rule, of some injury or focal softening, with resulting slow destruction of the cord. Following and accompanying this is a reparative process which may be called inflammatory, together with secondary degenerations. Hence *chronic myelitis* is ordinarily a combination of—

1. A necrotic and destructive process.
2. A reparative inflammatory process.
3. A secondary degenerative process.

In what is usually called compression myelitis the process is one not of inflammation at all, but almost exclusively of—

1. Destruction of tissue from pressure and œdema.
2. Secondary degeneration.

To resume, I wish to point out that the term *chronic myelitis* is used loosely and incorrectly for mixed processes that have little or no inflammatory element in them, but are a mixture of necrotic, degenerative, and reparative processes. I do not wish to deny, however, that true primary chronic myelitis does not occur.

I have only been able to show, gentlemen, that there are problems in neuropathology of enormous interest and practical importance. And I can only hope that my presentation of some of them here may give some further impetus to their study and to efforts which will end in their final and triumphant solution.

I append here a tabular view of the various scleroses of the spinal cord, assuming yet that the processes are fibroid and not general:

I. *Primary Degenerative Scleroses.*

1. Posterior spinal sclerosis, locomotor ataxia.
2. Lateral sclerosis? spastic paraplegia.
3. The combined scleroses, Friedreich's ataxia, ataxic paraplegia, irregular forms.
4. Multiple sclerosis.
5. Progressive muscular atrophy and amyotrophic lateral sclerosis.

II. *Secondary Degenerative Scleroses.*

Of cerebral origin, lateral descending.

Of spinal origin, ascending and descending.

Of posterior root origin, posterior ascending.

III. *Inflammatory Scleroses—so called.*

- |                               |                     |
|-------------------------------|---------------------|
| Acute primary myelitis,       | } very rare.        |
| Chronic primary myelitis,     |                     |
| Acute secondary myelitis,     | } the common forms. |
| Chronic secondary myelitis,   |                     |
| Chronic compression myelitis, |                     |

These are mixed processes of softening, inflammation, and degeneration.

## DISEASES OF THE URINARY APPARATUS.

By JOHN W. S. GOULEY, M. D.,

SURGEON TO BELLEVUE HOSPITAL.

(Continued from page 11.)

### PART I.—PHLEGMASIC AFFECTIONS.

#### SECTION II.—SPECIAL CONSIDERATIONS.

##### VII.

##### PROSTATITIS AND BULBO-URETHRAL ADENITIS.

PROSTATITIS—phlegmasia of the vesical prostatic body—may begin and end in the glandular part (parenchymatous prostatitis); it may thence extend to the interstitial connective and muscular framework of the prostate body (diffuse prostatitis), or it may occur in the peripheral connective tissue (periprostatitis). The phlegmasia may be superacute, acute, subacute, or chronic.

*Causes.*—Prostatitis may arise from urethritis, from venereal excesses, from the contact of some irritant with the mucous membrane of the prostatic region of the urethra, such as often repeated strongly astringent injections in the treatment of "gonorrhœa," from external injury, from violent catheterism, or from exposure to cold and dampness. The superacute and acute types are of very rare occurrence, and generally caused by the extension of acute or superacute urethritis into the prostatic ducts and follicles, whence the phlegmasia diffuses itself into the interstitial substance, and sometimes extends into the peripheral connective tissue. This is sometimes excited by the so-called abortive treatment of "gonorrhœa" by the injection of a strong solution of nitrate of silver. The subacute type affects at first the parenchyma only, but later invades the interstitial substance, and may gradually pass into the chronic type.

These several types of phlegmasia are apt to leave the prostate in a very seriously damaged state, such as follows: destruction of a considerable proportion of the glandular substance, induration, shriveling, etc.; still there are many cases that end in resolution without apparent injury to any part of the organ.

*The chief symptoms of the acute types of prostatitis are,* in the beginning, a sense of weight in the perineal region; increased frequency and difficulty of urination; pain referable to the urethro-vesical orifice; and a sense of fullness in the rectum, with tenesmus. When the affection is consecutive to urethritis the patient notices a cessation of the discharge, which is ordinarily the case in most of the consequences of urethritis. In the course of two or three days all these sensations are greatly intensified. The rectal tenesmus is much increased, and the urgent desire to empty the bowel is ungratifiable by reason of the prostatic swelling. The dysuresis and stranguria become very distressing; finally, ischuria supervenes, and there is much pain in the lumbar region and along the course of the sciatic and anterior crural nerves, from the fast-accumulating urine in the bladder. Any pressure in the perineum gives a sharp pain, which is acutely felt at the extremity of the urethra—such as that experienced when a calculus comes in contact with the urethro-vesical orifice.

Trachelocystitis is almost always associated with pros-

tatitis, and two other unwelcome guests—gonecystitis and orchitis—sometimes intrude themselves to further distress the sufferer.

The little urine passed spontaneously before the advent of ischuria is acrid, high-colored, purulent, and at times bloody.

Exploration with the finger introduced into the rectum reveals much swelling, tension, heat, and hardness of the prostate, which nearly fills the lower end of the rectum. The slightest pressure made with this finger causes great suffering to the patient, the pain extending to the glans penis.

The diagnosis of acute prostatitis is based upon the analysis of the symptoms detailed above and upon the rectal exploration.

*Progress.*—Acute prostatitis generally resolves in the course of three or four weeks, but sometimes suppurates. The supracute type almost always suppurates.

The subacute type is slow in resolving, and sometimes ends in an abscess or in multiple abscesses of very gradual development.

In the supracute and acute types the advent of suppuration may be predicted when the occurrence of rigors and febrile reaction is followed by throbbing pains in the rectum and perinaeum. The pus may find an outlet in the bladder, in the urethra, in the rectum, or may point forward toward the perinaeum or backward toward the peritoneal cavity. The relations of the prostate to the bladder render possible the discharge in this viscus of an abscess pointing superiorly and posteriorly. The directions most commonly taken by the pus are toward the urethra and toward the rectum. When the abscess opens on the floor of the urethra by several small orifices, and freely discharges its contents, no harm ensues, but when there happens to be a large opening, the dangers of destruction of the whole prostate by the urine, and of consequent pyosapramia, are great.

A case illustrating this point occurred in 1864 at Bellevue Hospital. The patient, a young man, was suffering from retention of urine consequent upon a prostatic abscess. For his relief a silver catheter was introduced, but met, in the prostatic region, with an obstruction, which was, however, overcome, the incidental pressure causing the instrument to suddenly advance about an inch, when two ounces of creamy pus flowed, but the bladder was not entered. From that time the bladder relieved itself spontaneously. Symptoms of pyosapramia supervened, and the patient died in two weeks. The necropsy revealed a ragged opening in the floor of the urethra leading to a large cavity, with sloughy walls, containing stale urine and pus. The whole prostate was disorganized.

When the abscess points toward the rectum, digital exploration reveals fluctuation in that situation; the prostate, hard and tender during the periods of increase and stasis of the phlegmasic process, is now soft and little sensitive to the touch, one lobe or both lobes being in this state of suppuration.

In peiprostatitis, which is caused most frequently by violent catheterism, the abscess often points forward toward the perinaeum. The abscess very rarely points backward.

The great danger in such cases lies in its breaking into the peritoneal cavity. When the bladder is empty the rectovesical fold of the peritonæum descends to about half an inch of the base of the prostate, but as the bladder fills, the peritonæum ascends with it so that the antero-posterior space uncovered by peritonæum is doubled in extent. In some instances, however, as shown by the specimens exhibited, the peritonæum reaches and even overlaps the base of the prostate. These facts are sufficient to account for the occasional occurrence of peritonitis in cases of acute prostatitis.

*In the treatment of the acute types of prostatitis*, local antiphlogistic measures should be promptly adopted, the main indications being to prevent suppuration and hasten resolution. Antiphlogistic treatment is, however, applicable only during the stages of increase and stasis. Later—that is to say, when there are already signs of softening and suppuration—this treatment is of no avail, and may even be harmful.

In any case of acute prostatitis the first inquiry of the physician should relate to the condition of the bladder. If he finds retention of urine, he should lose no time in relieving the distended bladder. Unless the bladder is kept empty, any mode of treatment tending to favor resolution of the phlegmasic process in the prostate must inevitably fail, for the distended bladder mechanically impedes the venous circulation in its vicinity. Catheterism in cases of swollen prostates is often very difficult and requires the utmost caution and gentleness. The use of metallic catheters is unjustifiable in the vast majority of cases of retention of urine from acute prostatitis. The safest and most efficient instruments for this purpose are the soft, curved, so-called gum catheters, not larger than No. 9 of the English scale. Such catheterism is ordinarily required every five or six hours for at least a week. Recumbency is, of course, enjoined.

After the intestinal tract has been emptied, the rectum should be thoroughly washed. Immediately after the cleansing process three or four leeches should be applied to that part of the rectum underlying the prostate. This can be conveniently accomplished with the aid of the leech-tube devised by Dr. James S. Hughes, of Dublin. This tube is much better than those of Bégin, Henderson, and Craig. The following is Dr. Hughes's description of his leech-tube:

"The instrument . . . consists of a curved gun-elastic or gutta-percha tube, of about six inches in length, open at one extremity, closed at the other, the latter being rounded off and inverted or bell-shaped, and perforated with two or more conical holes capable of enabling the leeches to do their duty but not to escape through. The lesser curve of the tube is grooved or concave externally. The following is the mode in which the instrument should be used: The patient having been placed in the kneeling posture, the surgeon should pass the forefinger of his left hand, previously well oiled, into the rectum with a gentle rotatory motion, until it has reached the inflamed prostate; he then should take with his right hand the leech-tube, previously oiled and furnished with from one to four leeches, as the case might be, and pass it along the curved dorsal aspect of the

left forefinger to the exact spot where the leeches ought to be applied, the left forefinger acting as a director to the leech-tube, and forming with it, as it were, one instrument, the concave surface of the tube traversing and adapting itself to the convex surface of the finger. By this simple contrivance leeches can be brought and kept in contact with the rectal surface of the prostate without danger of their escaping from the instrument into the intestine, on the one hand, or of the tube becoming blocked with feculent matter on the other." These leech-tubes of Dr. Hughes's have lately been made of glass.

There may be circumstances forbidding the application of leeches to the rectal mucous membrane. In such cases, ten or twelve leeches may be applied to the perineal and anal regions, the effect of either mode of leeching being to disgorge the præ-prostatic plexus of veins and thus relieve the blood stasis in the capillary vessels of the prostate.

When it is judged that a sufficient amount of blood has escaped after the dropping of the leeches, the rectum should be cleansed and then packed with ice, which should be renewed as fast as it melts, means, such as the introduction of a gum-elastic tube, being provided for the escape of the water if it does not flow freely during the insertion of new ice suppositories. This ice treatment should be continued two, three, or four days, according to the necessities of the case. The relief afforded by the cold is great, and enables the patient to obtain much refreshing sleep. During the day the ice is renewed every half-hour if need be, but once every two hours in the night generally suffices, the patient waking to ask for a renewal of the ice suppositories. Should it not be possible to continue the use of ice by the rectum, an India-rubber bag filled with ice could be applied to the perinæum, and the benefit of dry cold thus obtained.

During these three or four days catharsis should be kept up by drachm doses of sulphate of sodium, dissolved in three ounces of hot water, every four hours. Tartarized antimony was formerly given in doses of one eighth of a grain every four hours, but this can now be judiciously replaced by diaphoretics that cause less depression than the antimonial salt.

To insure diuresis, from forty to sixty grains of bicarbonate of sodium should be given in six ounces of water three and even four times daily. This alkali, in such cases, acts as an antiphlogistic and as a diluent counteracting the acidity of the urine. A full dose of morphine by the mouth or hypodermically serves the purposes of relieving pain and inducing sleep. The diet should be restricted to broths and bread and milk.

If resolution begins within a week from the onset of the phlegmasia, it may be promoted by hot enemata, hot fomentations to the hypogastric and perineal regions, and a hot hip bath of five minutes' duration every night. Internally, five grains of chloride of ammonium may be given four times daily, and mild saline aperients administered every morning. Under favorable circumstances, in the course of two or three weeks from the beginning of resolution the prostate nearly regains its normal condition. Re-constituents and a generous diet are then indicated.

When resolution fails and suppuration occurs, the sooner

the pus is allowed free outlet the better. If the pus is discharged into the urethra, the greatest care should be taken to prevent the urine from entering the abscess cavity. The patient should not be allowed to urinate spontaneously, but the catheter introduced, as before, every five or six hours, for two or three weeks after the first gush of pus, so as to give time for contraction of the cavity and healing by granulation from the bottom. If the pus points toward the rectum, a Sims speculum should be introduced and a sufficiently free incision made into the abscess, whose cavity should be well disinfected and loosely packed with antiseptic gauze. If the cavity is very small, it may be left to granulate without packing. When, as in periprostatitis, the abscess points toward the perinæum, if fluctuation is detected by perineal palpation, a central perineal incision answers the purpose of emptying it; but if the indications of suppuration are entirely by rectal exploration, a crescentic incision, followed by careful dissection between the urethra and rectum, is required to safely reach the purulent focus, after whose evacuation and cleansing with peroxide of hydrogen solution the same dressing may be made as in the other cases. As a general rule, the parts heal by granulation in the course of four or five weeks.

*Prostatitis from exposure to cold and dampness* is not an uncommon occurrence among elderly men whose urination may or may not have been impeded before such exposure. From the cases observed, three are selected to illustrate the ill effects of a phlegmasia which involves the mucous membrane of the prostatic region and of the urethro-vesical orifice, together with a very superficial layer of the prostatic parenchyma, causing an œdematous swelling of the mucons membrane that may be likened to œdema of the glottis from the suddenness of its invasion and rapidity of swelling. In two or three hours after the exposure there is frequent and difficult urination, and, within six or eight hours, retention of urine.

A patient, sixty-six years of age, who had never had any hindrance to urination, left the city in apparent good health to spend the night at his suburban residence on a cool mid-September evening. From the railway station to his house the distance is about a quarter of a mile. He walked briskly and was somewhat heated on his arrival. He remained for a time out of doors, and, desiring to urinate, exposed his pudendal region in the act of relieving his bladder. At that moment he experienced a distinct chilly sensation, and thought nothing of it until later in the night, when he was several times obliged to urinate. Before sunrise the frequency of urination had greatly increased, so that he was disturbed every ten minutes, suffering much burning pain at each act. He returned to the city early in the morning, when he was unable to pass a single drop of urine. The catheter was used, much to his relief, but he could not afterward urinate spontaneously. He died within six months from the date of the attack. The necropsy revealed a hard, thick, bar-like obstruction at the urethro-vesical orifice, but the prostate was very little enlarged. This urethro-vesical bar indicated that supramontanal enlargement had begun, but was not sufficient to interfere with urination until the advent of the acute phlegmasiac swelling.

It is evident that the continuance of the obstruction was owing to an abundant unresolved exudate.

A similar accident happened to a patient, fifty-eight years of age, who sat for several hours in the evening on the piazza of a watering-place hotel late in the autumn, the air being chilled and the fog dense. During the night he was unable to urinate, and from that time was compelled to rely upon the catheter for relief. He had never before had any impediment to micturition.

A patient, sixty-three years of age, who in the course of the previous ten years had several times suffered from retention of urine, imprudently sat during the evening on the stone steps of his house late in the month of August. At length, feeling chilly, he went to bed. In the morning he was unable to urinate, and from that moment required frequent catheterism for nearly two months, after which he was able to urinate spontaneously, but could not completely empty his bladder, the urethro-vesical obstruction having become permanent. At the time of the retention of urine the prostate was considerably swollen, but was afterward reduced to nearly its normal size, except, of course, in the supramontanal region.

The same phlegmasia occurs very commonly in young and middle-aged subjects from exposure to cold and dampness during the decline of acute urethritis or during a debauch. This has been improperly called acute inflammatory stricture. The bladder, suddenly distending, causes great suffering, and the patient is likely to apply for relief during the first day. Not many years ago these cases were subjected to vigorous antiphlogistic treatment, but of late years the first care has been to empty the bladder by the prompt introduction of a gum catheter. This is followed by the use of ice suppositories for a few hours, and then by free catharsis. Sometimes a single catheterism suffices, but it is ordinarily advisable to enjoin two or three days of recumbency and the free use of diluent beverages. Deliquescence, or at least very rapid resolution, generally occurs in these last-named cases.

THE CHRONIC TYPE OF PROSTATITIS—variously named catarrhal prostatitis, mucous prostatitis, follicular prostatitis, canalicular prostatitis, prostaticorrhœa, etc.—is of much more common occurrence than the acute types, and begins in the mucous membrane of the prostatic sinus, reaching finally the utriculus, the prostatic ducts, crypts, and interstitial tissues. Its development is so gradual that often it is not recognized for a long time. It is ordinarily one of the phases of chronic urethritis, whether this urethritis be the outcome of acute urethritis, of masturbation, or of venereal excesses, or whether it is excited by hyperlithuria, by the lodgment of urinary calculi in the prostatic sinus, by chronic cystitis, by a urethral stricture, by frequent catheterism, by the extension of phlegmasia from the seminal vesicles, by the irritation caused by hemorrhoids, or by the prolonged retention of catheters in the bladder. Chronic prostatitis may also be a sequel of acute prostatitis. Although chronic prostatitis ordinarily affects young and middle-aged men, it not infrequently occurs among elderly men suffering from prostatic enlarge-

ment. In these cases it is the outcome of the frequent catheterism rendered necessary by the urethro-vesical obstruction.

The chief symptoms of chronic prostatitis are sensations of fullness and weight in the perinæum and rectum, perineal tenderness experienced in the sitting posture, dull pains in the perineal and anal regions increased by active exercise and sexual contact, pains in the lumbo-sacral region and in the lower extremities, occasional painful seminal emissions, costiveness, frequent urination, painful urination particularly at the close of the act, a slight muco-purulent, yellowish urethral discharge, and, during defecation, a free urethral discharge of milky prostatic fluid rendered slightly viscous by the admixture of the secretion of the urethral mucous glands. The characteristic odor of the mucus of these glands is imparted to the prostatic fluid and semen, which, by themselves, are odorless. To this last symptom the name prostaticorrhœa owes its origin, and from this symptom arose the erroneous popular belief that the glairy fluid in question was semen. To some patients this discharge of prostatic fluid is a source of much anxiety. They imagine themselves affected with seminal incontinence and even impotency, and become the easy victims of designing charlatans. In certain cases the sexual act is attended with so much pain that it is at last abandoned and in time the desire is abolished. Such patients become sullen and lead a life of seclusion, their thoughts are centered upon their supposed infirmity, and their forebodings are of countless imaginary evils. This mental state is more likely to exist in men whose health is already impaired, but undoubtedly causes its further deterioration. Their sedentary life leads to loss of appetite, disturbance of digestion and consequent hyperlithuria, costiveness, leucomainal toxæmia, languid circulation, etc.

The physical characters of chronic prostatitis become known partly during life and partly after death. Beginning in the mucous membrane of the prostatic sinus, it gradually invades the ducts, the crypts, and the interstitial tissues. In some cases the prostate is soft, in other cases it is indurated. Either condition may be ascertained during life by digital rectal exploration.

In a large proportion of cases of chronic prostatitis the mucous membrane of the prostatic sinus is in a granular state, which can be seen with the aid of the urethroscop. In some cases small retention cysts from the occlusion of ducts, or degeneration cysts from isolated gradual degenerative processes, or abscesses from sudden local necrosis, are slowly developed in the substance of the prostate and are detected by rectal exploration with the finger, and by subsequent puncture with a small trocar. Very rarely it is found that the greater part of one lobe is destroyed by an abscess.

Dissection of the prostates of patients affected with chronic prostatitis, dying from some intercurrent disease, has revealed the granular condition to which reference has already been made, the granular mucous membrane being red from congestion up to the vesico-urethral orifice, a spongy, soft state of the prostate, which is somewhat larger than natural and may contain degeneration cysts or small

abscesses, or a hard state of the prostate, which is decreased in size and sometimes contains retention cysts, and the utriculus occasionally filled with pus.

When the prostatic crypts have become involved in the phlegmasic process, their microscopic sympexia are set free by the exudate and are then metamorphosed into calculi which, by the accretion of concentric phosphatic layers, attain in time very considerable dimensions. In one case a thousand such calculi, each about half a millimetre in mean diameter—except three, one of which weighed three grammes fifty centigrammes, and the other two weighed together twenty centigrammes—were removed, through a perineal incision, from the prostate of a man twenty-six years of age. In another case eighteen prostatic calculi were similarly removed from a man fifty-four years of age. These eighteen calculi averaged seven millimetres, the largest measured ten by fourteen millimetres, the smallest three millimetres; the whole weighed one hundred and forty grains—about nine grammes. Both patients were cured by the operation.

In perhaps five per cent. of the prostates dissected during the past twenty years, several small calcareous concretions have been found occluding the mouths of prostatic ducts or lying free in the prostatic sinus, and in a much greater percentage of these prostates, particularly those of elderly men, the calcareous transformation was verified by the inordinately gritty state of the substance of the organ. This it seems is evidence of chronic phlegmasic action sufficient to disturb or even to kill the sympexia, which then become foreign bodies. It is when these foreign bodies are not speedily cast away that they receive successive layers of calcium phosphate until they greatly dilate and finally destroy most of the prostatic crypts.

In chronic prostatitis arising from narrow urethral strictures, not only are the ducts dilated by the reflux urine, but the prostatic sinus also undergoes expansion. One of the specimens exhibited is from an extreme case of ectasia, the prostatic sinus being dilated to the extent of containing at least thirty grammes (one ounce) of fluid, the substance of the prostate being soft and spongy.

*The diagnosis of chronic prostatitis* is based upon close analysis of the symptoms, examination of the urine, physical exploration, the anatomical characters, and the history of the affection. The symptoms can be rightly interpreted only in connection with the examination of the urine and the physical exploration.

The urine of patients affected with chronic prostatitis is generally somewhat cloudy, owing to the presence of pus and epithelium from the prostatic region and sometimes also from the bladder. The many shreds and scrolls so commonly seen in this urine are shown on microscopical examination to consist of pus, epithelial cells, and some blood-cells held together by mucus. Among these shreds and scrolls are sometimes seen long cylindrical bodies which appear to be casts of the smaller prostatic ducts. Great quantities of octaedra of calcium oxalate are frequently found in the urine of these patients; at times lozenges of uric acid, at other times the urates in great abundance. Microscopic sympexia cast away from the prostatic crypts

are often found in this urine, particularly in the case of elderly men.

A convenient method of obtaining pus from the prostatic sinus for microscopical examination is to introduce into the sinus of the urethral bulb a hollow, soft, No. 12 English bougie, with an acorn-shaped vesical extremity, with three or four perforations at the base of the acorn, and to syringe in four or five ounces of warm water for the purpose of washing away, by the retrograde current, the pus that may have accumulated in the spongy urethra. This accomplished, the bougie is carried onward as far as the urethro-vesical region and then withdrawn. The pus found coating the base of the acorn is then placed upon a glass slide, properly covered, and subjected to microscopic inspection. Mixed with this pus are many epithelial cells, perhaps some casts of the smaller prostatic ducts, and possibly a few sympexia, but no spermatozooids.

The first step in physical exploration is digital rectal examination. By this it is ascertained if the prostate be tender or insensible to the touch, hard or soft, decreased or increased in size, smooth or nodular; if nodular, whether the nodules be firm from organized plasma, doughy from purulent accumulation, tense from cystic formation, or of stony hardness from the presence of calculi.

The next step in this exploration is an examination of the urethra for the purpose of excluding urethral stricture, trachelocystitis, or vesical stone. Chronic prostatitis being sometimes the indirect outcome of urethral stricture, the urethra should be explored with a bulbous bougie to make sure of the existence or of the non-existence of stricture. The granular condition already referred to can be ascertained with the aid of the urethroscope.

The sharp pain at the urethro-vesical orifice during urination or at the moment of entrance into the bladder of a bougie or catheter indicates the complication trachelocystitis, which is so frequent that the coexistence of these affections has given rise to the term chronic prostatocystitis. The persistent vesical pains simulate so much some of the symptoms of stone as to warrant an exploration of the bladder with a rectangular staff to clear any doubt in this respect. When the pain caused by the exploration is slight and confined to the prostatic region, the case may be regarded as uncomplicated chronic prostatitis.

*The treatment of chronic prostatitis* is varied in accordance with its different phases, complications, and consequences.

Uncomplicated chronic prostatitis attended with a flow of from a few drops to nearly a drachm of prostatic fluid during defecation, so common among continent men, and still more so among those addicted to masturbation, requires moral as well as local and constitutional treatment.

*The moral treatment* is the most difficult of the self-imposed tasks of the physician, who must employ much circumspection before he can pass judgment upon the needs of particular cases. In examining and advising any individual, he may exercise the greatest firmness, tempered, however, with patience, forbearance, and kindness. Thus he enlists the confidence of the sufferer, endeavoring to lead him to understand, first, that his local ailment is cura-

ble; second, that he is not suffering from seminal incontinence; third, that he is not impotent; and fourth, that he can not be cured unless he gives up the bad habits he may have acquired, and occupies his mind with subjects other than his ailments. When the patient is responsive to the moral treatment, more than half of the cure may be considered accomplished.

*The local treatment* of uncomplicated chronic prostatitis consists in irrigating the prostatic sinus once daily, with the object of washing away the mucus and pus which may have accumulated in the sinus and in the larger prostatic ducts. The fluid for irrigation should at first be a one-per-cent. watery solution of boric acid, using not less than four ounces of this solution for each irrigation. This often suffices in certain cases, but may be used with advantage as a preparatory step to more active measures when such are necessary. The manner of making this irrigation is to introduce a No. 8 or No. 9, English, uniocular, curved gum catheter into the membranous region of the urethra, and to slowly inject the fluid, which, passing through the prostatic urethra, dislodges and carries into the bladder the mucopurulent contents of the prostatic sinus. If any of the fluid flows out of the urethra beside the catheter, it is an index that the catheter has not reached the membranous region. In that case the instrument should be made to advance a little farther; then the injection surely enters the prostatic region and bladder. When the four ounces have been thrown in, the catheter is pushed into the bladder, whose contents are allowed to escape into a glass vessel to be examined for flocculi of muco-pus and epithelium, and to make sure that the cleansing process has been successful.

These irrigations are very effective also in the chronic prostatitis of elderly men. In many cases the prostatic sinus is filled by a plug of tenacious slime, which for hours is a source of irritation and of frequent prostatic spasms, until it is suddenly forced out by a stream of urine. The daily use of irrigations with the boric-acid solution almost invariably has the effect of breaking up this tenacious slime, or of preventing its accumulation. In case of granular urethritis of the spongy portion, it is wise to irrigate the whole canal. When these simple irrigations are insufficient to relieve the local distress, the use of steel sounds of increasing size has the double effect of dilating the canal and, by compression, of causing the granulations to disappear. The sound should not be passed oftener than twice each week. In conjunction with this process of dilatation, every third or fourth day the prostatic region of the urethra should be irrigated with a solution of nitrate of silver, one grain to the ounce, increasing its strength at subsequent sittings to two, three, and even five grains to the ounce of distilled water, and using only one ounce of the solution. The bladder should contain a few ounces of urine, so that the nitrate of silver may be decomposed and rendered harmless to its mucous membrane. The method of Guyon, by the instillation of five, ten, or twenty minims of nitrate-of-silver solution, from five to thirty grains to the ounce, is also employed in chronic prostatitis, but the use of a larger quantity of a weaker solution, such as one ounce, is preferable, as the fluid has a better chance of entering the prostatic

ducts, and it is not desirable that the strength of the solution exceed five grains to the ounce. Before making the injection the prostatic urethra should be well cleansed with pure water. The immediate effects of the injection are a severe burning pain in the prostatic region and frequent and almost irrepressible urination, lasting an hour or two hours. There may even be a slight hæmorrhage, which, however, soon ceases. Afterward the mucopurulent discharge is much increased, but lessens and nearly disappears in two or three days. It sometimes happens that after the first or second injection of nitrate-of-silver solution there are no longer any manifestations of chronic prostatitis, but, as a general rule, several injections are necessary to effect a cure.

Other substances have been used in solution for irrigation in chronic prostatitis, such as mercuric or zinc chloride, copper or zinc sulphate (five grains to the ounce), resorcin, otherwise known as metadioxybenzol (ten grains to the ounce), but they are not equal to nitrate of silver in solution of moderate strength, the great advantage of nitrate of silver being that it is decomposed and becomes innocuous as soon as it has caused coagulation of the albumin of the superficial layer of epithelial cells.

In some cases of chronic prostatitis, owing perhaps to a slight imprudence or error in diet, the urethral discharge greatly increases, becomes creamy, simulating acute virulent urethritis. There are inordinate frequency and pain in urination, and a train of symptoms which are very apt to mislead the inexperienced. Such patients should not at first be subjected to local treatment, as it would be likely to aggravate the phlegmasia and cause some serious complication. Three or four days of rest and the free use of diluent drinks generally suffice to cause the cessation of all these phenomena. Then the local treatment may with safety be applied.

It is scarcely necessary to say that no success in treatment can be attained in complicated cases unless the complication is treated at the same time. If chronic cystitis exists, it demands special local treatment; if a urethral stricture should be detected, dilatation, division, or urethrotomy might be required. If painful hæmorrhoids or anal fissures are the complication and perhaps also the cause, they should be appropriately treated. When prostatic calculi have already formed, they should, if possible, be removed without delay.

In those cases attended with constant dull pain in the perineal region and tenderness of the prostate it is proper to use counter-irritants for five or six weeks. Painting the perineum with strong tincture of iodine, first on one side of the rhaps, then on the opposite side, every two or three days, often answers the purpose; otherwise vesicating colodion may be similarly applied, avoiding the scrotum and anus, and covering the vesicated part with a thick layer of absorbent cotton. Suppositories of opium and belladonna may be occasionally used to relieve pain.

Small cysts or abscesses of the prostate may be tapped, by way of the rectum, with a small trocar and irrigated with peroxide-of-hydrogen solution.

*Constitutional medication* is necessitated by the generally

impaired health of most sufferers from chronic prostatitis, and this medication is subject to such variations as may be indicated by the characters of the constitutional manifestations. The use of bitter tonics in conjunction with an improved diet is likely to sharpen the appetite and facilitate digestion. Active treatment for hyperlithuria may be necessary. Iron and quinine are of value as reconstituents. Laxatives soon have the effect of preventing fecal accumulation, and afterward equal parts of tincture of chloride of iron, tincture of cantharides, and fluid extract of ergot, given in doses of ten minims twice daily, complete the internal medication. Then frequent general bathing followed by frictions, and increasing exercise, comprise the hygienic measures.

**BULBO-URETHRAL ADENITIS.**—Before examining the phlegmasic processes to which the bulbo-urethral glands are subject, some points in their history, special anatomy, and physiology may with profit be studied. These glands, the analogues of the vulvo-vaginal glands, were discovered by Méry, and a very brief description of them was inserted in the *Journal des savants*, June, 1684. Fifteen years after this, in 1699, Cowper published, in the *Philosophical Transactions*, a note on these glands, and in 1702 gave of them a detailed description, and they have since borne his name. Several other anatomists laid claim to their discovery and each gave them a new name, such as little prostates, accessory prostates, inferior prostates, antiprostates, etc. In 1849 Gubler published, as his inaugural thesis, an exhaustive study of the anatomy and the phlegmasia of these glands, and adopted for them the name of bulbo-urethral glands on account of their site. They consist of a pair of compound racemose glands encapsulated by fibrous tissue, situated behind the urethral bulb, between the two layers of the triangular ligament, in the substance of the ischio-urethral muscle, and beneath the membranous portion of the urethra. They are generally about one millimetre on each side of the median line, but sometimes in contact. They are globular, discoid, or ovoid in form, and from five to eight millimetres in mean diameter. In the fœtus they are proportionately much larger than in the adult. In some of the lower animals, as the *Rodentia*, they are very large. In color they are pinkish yellow, in consistence firm and elastic.

In structure they are similar to the racemose glands and consist of roundish cellules, ranging from the one six-hundredth to the one three-hundredth of an inch in diameter, grouped around small ducts after the manner of bunches of grapes, the whole being bound by connective tissue and capillary blood-vessels. The cellules and ducts are lined by a cubical epithelium. The ducts of several primary lobules unite and form larger ducts which end in a common excretory duct.

Each gland has a single common excretory duct which emerges from the anterior extremity of the gland. This excretory duct varies in length from three to six centimetres, and in diameter from a quarter of a millimetre to one millimetre. As it emerges from the gland, this duct enters the substance of the urethral bulb and traverses it obliquely from behind forward for the space of one centimetre, where

are found the accessory lobules which led Cowper to believe in the existence of a third gland. The duct then takes a nearly longitudinal course underneath the urethral mucous membrane for a distance varying from two to five centimetres and ends in a very narrow orifice beside the median line a little in advance of its fellow, the two very rarely having a common orifice. This orifice is sometimes so small as scarcely to admit a hair. It is generally very difficult and often impossible to find this orifice even in carefully dissected fresh specimens. The mucous membrane of the ducts is surmounted by a cubical epithelium resting upon a thin membrane surrounded by longitudinal and circular bands of smooth muscle tissue to be found also among the divisions of the duct in the substance of the gland.

The secretion of the gland in the natural state is colorless and viscid, and in pathic states becomes opaline or even markedly turbid, without, however, losing its viscidly. This secretion, whether in health or in disease, is much more consistent than that of any of the uro-genital glands, and it is this consistence which distinguishes it so well from the others. This viscidly of the mucoid fluid is such that it is easy to draw it into threads from ten to fifteen centimetres in length. It is of alkaline reaction, and when rubbed has the property of frothing like soap-suds.

These glands are annexes of the genital as well as of the urinary apparatus. As genital organs, their secretion, profuse at the beginning of the act, serves to lubricate the glans penis to facilitate intromission, and, continuing during the act, serves to dilute the semen. As urinary organs, their secretion is among those designed to lubricate, and so protect the urethral mucous membrane.

*Bulbo-urethral adenitis*—phlegmasia of a bulbo-urethral gland—is ordinarily the outcome of urethritis, but may also arise in consequence of a blow upon the perinæum or of an injury of the gland's duct by the accidental penetration of a capillary bougie. The left seems to be more commonly attacked than the right, and very exceptionally are both glands affected. The phlegmasia may be acute or chronic. In the great majority of cases the acute type resolves in a short time, suppuration being a rare termination. The chronic type is more frequent than it is generally supposed to be, and often constitutes one of the varieties of chronic urethral discharge. Observation of this chronic discharge, with induration and enlargement of the glands, led Cowper and several of his contemporaries to believe that "gonorrhœa" was often caused by phlegmasia of the bulbo-urethral glands, whereas this phlegmasia is in reality one of the occasional consequences of "gonorrhœa."

Acute bulbo-urethral adenitis consequent upon acute urethritis is often overlooked, because the perineal pain and tension which so frequently occur on the second, third, or fourth week of urethritis are not rightly interpreted, or not considered worthy of attention, or perhaps they are attributed to a purely neurotic condition, and the cessation of the pain is believed to be due to the remedies that may have been administered, whereas, in the majority of cases, the pain ceases owing to rapid resolution of the phlegmasia.

*The subjective symptoms* of this mild type of bulbo-

urethral adenitis are painful tension in the perineal region on the affected side, tenderness to pressure while the patient is in the sitting posture, pain during walking exercise, from friction by the clothing, and more or less burning sensation in the region of the urethral bulb.

*The objective symptoms* are slight tumefaction corresponding to the situation of the gland, which, though hard and increased in volume, is movable; moderate compression of the gland with the finger, causing more or less pain, which is propagated to the urethra. There is no febrile reaction, no redness of the skin.

*The progress* of acute bulbo-urethral adenitis is ordinarily very rapid. As a general rule, resolution begins in a few days. Otherwise, suppuration is established in the course of ten days or, at most, two weeks. The phlegmasia, at first confined to the gland, finally extends beyond its fibrous capsule and into the ambient connective tissue, and there is periadenitis. Then the gland can no longer be felt, for it lies in a pus cavity. The abscess sometimes encroaches upon the opposite side, and extends forward to the scrotum. The skin is œdematous, becomes red, then livid in the center of the swelling, and at length ulcerates and gives issue to the pent-up pus, and later, perhaps, to urine, unless timely surgical aid had been obtained. The beginning of the suppurative process is known by febrile reaction, throbbing perineal pains, and increase of tenderness and tension.

Among the consequences of neglected bulbo-urethral adenitis are retention of urine from mechanical compression of the urethra by the abscess, perforation of the urethra and urinary fistula, and obliteration of the excretory duct of the gland.

*The diagnosis* is easy during the period of increase of the phlegmasia. The situation of the swelling, its mobility, its tenderness, viewed in conjunction with the history of the case, demonstrate the existence of bulbo-urethral adenitis. But when periadenitis is superadded, it may be confounded with urinary or simple abscess or a boil. Here, again, the history of the symptoms comes in aid to make certain the true nature of the swelling. If, after the abscess has been opened, a fistula persists for months and discharges a very viscid fluid, particularly at the beginning of sexual contact, it may be asserted with confidence that this fistula springs from the gland or from its duct, which may be obliterated at its anterior portion. A fistula giving issue also to urine indicates perforation of the urethra.

*The treatment of acute bulbo-urethral adenitis* during its period of increase should be antiphlogistic, consisting in the application of half a dozen leeches to the perinæum, after which the ice-bag is to be used for three or four days. If at the expiration of that time resolution has not begun, the swelling and tension have increased, and the pain is throbbing, an incision should forthwith be made into the substance of the gland. The patient is placed in the lithotomy posture, a narrow, straight bistoury is plunged into the swelling, at its most prominent point, and the wound is enlarged to half or three quarters of an inch in withdrawing the instrument. A few drops only of pus or none may flow, but the tension will have been relieved and

perforation of the urethra prevented by this timely incision, without which it is almost certain to occur. As soon as the incision is made the cavity of the abscess should be irrigated with peroxide-of-hydrogen solution until the returned fluid is clear. The wound is then dressed antiseptically. Under favorable circumstances cicatrization is complete in the course of ten days. In the case of an abscess containing an ounce or two of pus there is very likely perforation of the urethra, and the healing process is necessarily long. To insure cicatrization, the patient is not allowed to urinate except through a catheter. In the case of a persistent fistula springing from the bulbo-urethral gland or its duct, attempts have been made to stop the flow of viscid mucus by injecting through the fistulous orifice different fluids designed to impair the structure of the gland, such as nitrate of silver, tincture of iodine, etc., but generally without success. Excision of the gland was proposed by Gruget, but it does not appear that he has ever performed this operation, which, from the situation and relations of the gland, would present no great difficulties, and which is justifiable in view of the facts that the affected gland is of no further use, and that the constant discharge of the viscid mucus is a source of no little annoyance to the patient.

(To be continued.)

#### NOTE ON THE TREATMENT OF INFLUENZA.

BY J. HARRISON METTLER, A. M., M. D.,  
CHICAGO.

As it seems probable that we are to have another outbreak of the grip, though less extensive and milder in degree, this winter, it is judicious for us to occasionally compare notes in regard to its treatment. Two years ago, when the epidemic first appeared in all its pristine severity, I endeavored, out of a large experience with it, to formulate some definite line of treatment that might be more or less applicable to all cases. I accomplished this to a certain extent, to my own satisfaction, but last winter, and so far this winter, I have met with such unusual manifestations of the disease that I have learned to recognize the fact that no two cases can be cared for in precisely the same way.

When the affection first appeared, the high fever and bronchitis seemed to me to be its most prominent features. Other symptoms—such as the aches and pains in the back, headache, coryza, and nervous depression—were common enough, but certainly not so universal, in my experience, as the fever and bronchitis. Indeed, many able practitioners at that time believed that the majority of the cases were nothing more nor less than severe general colds with bronchial cough. The cases that are falling under my observation now, however, portray an almost different type of the disease. The same fever and bronchial symptoms are present, but to a less marked extent, while the headache, the bodily pains, the bizarre sensations of all sorts, and especially the nervous depression, are much more loudly complained of. In a word, the present manifestation of the

epidemic partakes more of the neurotic type. Its character rather than its severity differs. Frontal headache immediately above the eyes and of a most distressing nature is very common; with this there is little if any nasal catarrh. Pains of various character are felt in the chest, but there is very little cough, no difficulty of breathing, and absence of the physical signs of pulmonary trouble. The pains in the loins and back of the neck are especially frequent and intolerable. Pain is not infrequently complained of in the lower part of the abdomen, and one of my patients says that she is most distressed by a peculiar, heavy aching pain around the thighs just above the knee. I do not find the temperatures rising so high now as when the epidemic first came upon us. In one of my cases the fever strangely disappears almost entirely if the patient gets up and exerts herself, whereas it rises to 102° and 103° as soon as she lies down and becomes quiet again. The appetite usually fails, while the action of the bowels remains normal. While these curious symptoms are severe and most annoying, the condition in my cases is less alarming as a whole than it was two years ago. In general, it may be said that the fever then was of the sthenic type, while now it is of the asthenic. For infants, aged people, and those debilitated by other chronic and intercurrent maladies, the one is no less a dangerous form of influenza than the other. Now, as then, such cases arouse anxiety and should be afforded unusual attention.

As soon as I see a simple case of the grip I at once recommend absolute mental and physical rest. Rest and quiet I have found the *sine qua non* for the successful treatment of the disease. Not only is this necessary to prevent possible complications, but it is desirable to counteract the nervous depression. A patient who consents to remain indoors until the attack has worn off is, of course, not liable to contract the pneumonia which renders this disease so fatal; and the absence of all excitement to the nervous system enables the proper remedies to effect a speedy and satisfactory cure. I am satisfied that we can not be too imperative with our patients in regard to this matter of rest. When I meet with one who is inclined to be argumentative, I even go so far as to say that I am certain I can cure him in four or five days at the most if he will remain quiet; but if he insists upon being up and attending to his business, it will take at least two weeks to effect the same result, let alone the risk of contracting a fatal complication. A plain statement of this sort I usually find restores to me the needed authority, and the patient is ready for the further treatment.

In the absence of the Turkish bath, I order the patient to take a hot bath that same night just before retiring. I am careful to explain that I mean as hot as he can bear it and only for a few moments. He must then rub himself thoroughly with a rough towel, take some stimulus, and place himself in bed beneath heavy blankets. If there has been some elevation of temperature, I do not forego the bath, but I administer in the early part of the evening or late in the afternoon about eight or ten grains of quinine. This acts as a febrifuge and stimulus. Immediately after he is in bed he takes a pill containing extract of opium,

one fourth to one half a grain; camphor and ammonium carbonate, each two grains. This relieves the pain, induces sleep, favors free diaphoresis, and stimulates. Upon visiting the patient next morning I have generally found that the night's rest has resulted in a marked improvement in his subjective feelings. The greatest trial at this time is to prevent him from getting up and going at once to his daily occupation. I remind him of my statements the last evening, and inform him that he is now ready to begin the regular course of treatment.

I urge him to remain in bed, but if the rooms are warm and he is feeling comfortable, I allow him to dress and lie upon the couch. Every two hours he must take some stimulus, either in the form of milk punch, eggnog, or brandy, whisky, or rum in sweetened water. Usually he will take the punch about three or four times a day and the pure stimulus in the intervals. Between the latter there is very little choice. If the bowels are inclined to be loose, I prefer brandy; if constipated, whisky. I have some patients who find that the stomach tolerates the rum better than either the brandy or the whisky. The quantity given each time need not be large, if the effect produced is satisfactory. One or two teaspoonfuls is quite sufficient in the average case. To this stimulation I sometimes add, particularly if the fever be a prominent symptom, a two-grain quinine pill to be taken four times a day. If there is simply nervous exhaustion with the various bizarre sensations previously referred to, with absence of febrile symptoms, I order, in place of the quinine, the syrup of the hypophosphites in stimulating doses, or a pill three times a day containing arsenious acid, gr.  $\frac{1}{40}$ ; strychnine, gr.  $\frac{1}{40}$ ; dried sulphate of iron, gr. ij; quinine, gr. j. If, in spite of this treatment, the fever shows a tendency to rise toward evening, bringing on a return of the headache, I leave with the patient a powder containing two grains and a half or five grains of phenacetin, to be taken every two hours until there is free diaphoresis and an indication of the fever declining. I have usually found this to occur after the second or third powder. The phenacetin is also analgesic and thus relieves the headache and other pains. Upon going to bed the patient takes the opium, camphor, and ammonium pill as he did the night before. If the fever has reappeared in the afternoon, in addition to this pill and the control of the fever by the phenacetin, he is to place his feet for fifteen or twenty minutes in a hot-water bath and then to wrap himself up in bed between blankets. He takes a light, nutritious diet with milk as its staple article every three or four hours during the day. No special attention is paid to the bowels or kidneys. With the regulation of the diet, *absolute rest*, and the above-described line of treatment, I have found the majority of patients with simple epidemic influenza to get rapidly well in three or four days. The patient is then cautioned about going out too soon and every suggestion offered to prevent his contracting the disastrous sequelae which seem to follow a too early resumption of an outdoor life. This line of treatment is explicit enough and adapted to the vast majority of cases so far as my observation has gone, but yet, as I said in the beginning, each case must be treated largely by itself and special indications met

with special therapeutic agents. If complications are present, such as bronchitis, pneumonia, or rheumatism, they must be treated by themselves as such affections usually are, with, however, this proviso: that it be remembered they are the complications of a state of extreme nervous depression requiring always the full and free use of stimulants.

4228 GREENWOOD AVENUE.

## COMPOUND FRACTURE OF THE SKULL AND WOUND OF THE ARM CENTER.\*

BY L. L. WILLIAMS, M. D.,

PASSED ASSISTANT SURGEON, U. S. MARINE-HOSPITAL SERVICE.

JOHN W., negro roustabout, aged twenty-three years, was admitted to the United States Marine Hospital, Memphis, Tenn., March 29, 1891.

Two days before his admission he received a blow from a heavy club on the right side of the head, and was unconscious for a short time after sustaining the injury. A compound fracture, with marked depression and extensive comminution, was found in the right parietal bone, at the center of the Rolandic region. The left arm below the elbow was completely paralyzed. There was slight motion at the shoulder and elbow. The intellect was unimpaired, and sensation was normal. Operation three hours after admission. An oval flap was raised and the fracture exposed. The area of depressed bone was circular in shape and as large as a silver half-dollar. Thirteen fragments of bone were removed; several of these were imbedded in the brain, and were extracted with some difficulty. The inner table of the skull was extensively comminuted, and, in order to remove all of the spicula, the opening in the bone was freely enlarged with the rongeur. There was a laceration of the surface of the brain three quarters of an inch long, with slight loss of substance. An irregular laceration of the dura, an inch and a half long, was sutured with fine catgut. The edges of the wound of entrance in the scalp were then carefully excised, and a short rubber drain placed in the resulting orifice. The oval flap was then adjusted, sutured with catgut, and a sublimate dressing applied. After recovery from the anæsthetic, the patient complained of various abnormal sensations in the left arm and leg. At times he felt as though these limbs were immersed in hot water, and when pinched had a sensation of pricking above the point pinched.

*April 2d.*—Wound suppurating; has slight motion in the fingers.

From this date until April 10th the patient was inclined to be somnolent, with occasional delirium. At times an uncontrollable tremor of the whole body, like a severe rigor, would come on. There was constant and severe pain referred to the back of the neck. The pulse varied from 46 to 52. The respiration was normal. The temperature never exceeded 37.4° C. [99.6° F.], and was for several days subnormal.

*11th.*—Has hernia cerebri; no delirium; pain in neck less severe; applied compression.

*13th.*—Hernia increased in size; there is now paresis of the left leg, and tongue deviates to the left; intellect not impaired; shaved off hernia at the level of the scalp and reapplied compression.

*18th.*—Has regained considerable motion in leg, and can ex-

tend the fingers and wrist to a slight degree. The hernia continued to increase in size in spite of treatment, and was shaved off three times. Nevertheless, the paralysis slowly improved. On April 28th elastic compression was applied. The tumor rapidly decreased in size and soon sank below the level of the scalp. The paralysis likewise rapidly improved.

*May 15th.*—Was suddenly seized with a peculiar sensation of throbbing in the floor of the mouth. Upon examination, the tongue was found to be the seat of violent clonic convulsive movements. He could protrude and withdraw it at will, but could not keep it still. A finger inserted between the tongue and the teeth of the lower jaw was firmly grasped on the left but not on the right side. The spasm was therefore unilateral—a true focal or "Jacksonian" epilepsy. The dressing was taken off and the gauze packing removed from the wound. The spasm ceased at once. The dressing was reapplied without the gauze drain and no further spasm occurred that night.

On May 18th he had clonic spasms of the left arm and leg lasting fifteen minutes. This was followed by temporary increase of paralysis, but in a day or two the lost ground was regained. Shortly after this the wound healed.

On July 16th the patient was examined as to the degree of paralysis remaining, and the following points were noted:

Motion at shoulder almost normal; can flex and extend the elbow and wrist; pronation and supination imperfect; can flex fingers, but can not completely extend them. All of the fingers of the left hand are partially anæsthetic, but not analgesic. Perception of heat and cold is normal; the tactile sense alone is affected. He picks up articles with difficulty—fumbles with them as a child would. With his eyes shut he can not pick up a book, and can not distinguish between a knife and a pencil held in his hand. There is marked rigidity in the muscles of the left arm and forearm, and has been ever since motion returned—a spastic condition which becomes more pronounced when voluntary motion is attempted. The forearm is flexed and extended slowly and in successive jerks. Pronation and supination, wrist movements, and movements at the shoulder are executed in the same manner. When told to flex and extend the wrist, he can not avoid at the same time flexing the forearm and fingers. He can not flex the forearm without flexing the thumb and fingers, but can extend the forearm with the fingers flexed. Can stand for only a few seconds on the left leg. The joints of the lower extremity can be flexed and extended easily, and the femur rotated inward and outward. In walking, however, the toes are turned inward. The knee-jerk and ankle-clonus are exaggerated on the left side.

When he was discharged, two weeks later, there was but little rigidity in the muscles of the shoulder, but the muscles of the forearm had not improved in this respect.

The spastic rigidity of the muscles of the arm, combined with paresis, as exhibited in this case, is quite similar to the condition that obtains in so-called spastic spinal paralysis, and is probably due to a like cause—viz., degeneration in the pyramidal tract and lateral column of the cord; in this instance a descending secondary degeneration, the result of partial destruction of the arm center. The persistence of numbness in the fingers has been noted in a number of cases involving injury of the cortical motor area, and would appear to indicate, at least, a very close relation between the centers for motion and sensation. The inability to pick up articles with the eyes closed, and the awkwardness manifested in picking them up at all, seem to indicate faulty co-ordination, although these symptoms may be partly due to anæsthesia of the fingers.

\* Read before the Tri-State Medical Association of Tennessee, Mississippi, and Arkansas, November 20, 1891.

In reviewing the operation, it is to be regretted that the lacerated brain tissue was not excised in the first instance. Primary healing might thus have been secured, and the subsequent loss of brain substance from suppuration and hernia avoided.

Since writing the foregoing I have seen this patient again. He is working on the levee, and is able to manage a dump-cart. The anaesthesia of the fingers and rigidity of the pronator muscles remain, and will, in all probability, be permanent.

REPORT OF  
A CASE OF TUMOR OF THE BRAIN,  
WITH AUTOPSY.\*

By CHARLES STEDMAN BULL, M. D.,

PROFESSOR OF OPHTHALMOLOGY IN THE UNIVERSITY OF THE CITY OF NEW YORK;  
SURGEON TO THE NEW YORK EYE INFIRMARY;  
CONSULTING OPHTHALMIC SURGEON TO ST. LUKE'S HOSPITAL AND TO  
ST. MARY'S HOSPITAL FOR CHILDREN.

In April, 1890, I was consulted by a gentleman, aged forty-five, on account of a difference in the size of the two pupils, which had then existed for nearly a year without any change, and which interfered somewhat with his comfort in reading. I had known the gentleman for many years, but had never examined him professionally. He was a man of very active mind, by profession a civil engineer, and of somewhat irregular habits. He had always been myopic and astigmatic and had worn glasses for twenty-five years. He had contracted a chancre fourteen years before, and had had numerous lesions of constitutional syphilis since then, but none of them severe. For five years he had had no demonstrable constitutional lesion, until about two years before I saw him. He then began to have some curious, ill-defined brain or nerve symptoms of which he could give no very clear description, but he stated that he was sure they arose in his brain. From the general ill-defined description furnished I concluded that they were probably attacks of *petit mal*, which were at times accompanied by transient loss of consciousness, which was never of long duration, but the attacks increased in frequency. There was no regularity in these attacks. There were at times lapses of memory of very varying duration. At no time was there any headache until a few hours before his death. When I saw him in April there was marked, though not complete, ptosis of the *right* upper lid and paresis of *both* internal recti. In the *left eye* the iris was moderately dilated and immovable, the pupil on this side being more than twice the diameter of the right pupil. With the right upper lid raised and the refractive error corrected, there was crossed diplopia, the right image being lower, and the two images were brought to a level by a prism of 2°. The internal recti were not completely paralyzed, but parietic. There was no paresis of any of the other ocular muscles. The difference in the size of the pupils had existed unchanged for nearly a year. R. E.  $\frac{3}{8}$  0: with sph. — D. 8  $\odot$  cyl. + D. 2.50 axis 90° =  $\frac{3}{8}$  0. L. E.  $\frac{5}{8}$  0: with sph. — D. 4  $\odot$  cyl. + D. 0.50 axis 90° =  $\frac{5}{8}$  0. There were small, irregular central opacities in both lenses. In the *right eye* there was a moderate case of neuro-retinitis with not much swelling of the disc, but with two or three small hæmorrhages in the retina near the margins of the disc. The fundus of the *left eye* showed merely the ordinary changes of a myopic eye. The field of vision was apparently normal in each eye, and there was no interference with the color sense. He was then under treatment by mercury and potassium iodide, and

the dose of the latter was increased to thirty grains four times a day. Under this treatment the neuro-retinitis and the muscular paresis slowly subsided, and finally entirely disappeared. During the summer he began to have attacks of vertigo, and in the early autumn these vertiginous attacks increased in intensity, and there appeared a hemianæsthesia of the left side which gradually became well marked. During the autumn there were a number of regular, well-marked epileptiform convulsions, and the lapses of memory became more marked. On November 14, 1890, I made another careful examination, and found that not a trace remained of the neuro-retinitis, or of the ptosis, or of the paresis of the internal recti muscles. The vision remained the same. A test of the dynamics of the muscles showed for 18 inches a convergence of 12° and a divergence of 5°. For 20 feet there was no convergence at all, and a divergence of 5°. There was no diplopia at any distance. His intelligence was apparently unaffected, except for the lapses of memory. The condition of the left pupil had remained unchanged. There was no loss of power in any of the extremities, but the hemianæsthesia was very marked. I had previously made a diagnosis of pachymeningitis, and a prominent and very careful neurologist had made a diagnosis of multiple sclerosis of the brain. The patient remained in about the same condition until the night of January 28, 1891. He had gone to bed feeling as well as usual, and woke suddenly about two o'clock in the morning shrieking with severe pain in the occipital region. He remarked that this was the first attack of pain in the head which had occurred. He became rapidly delirious, then sank into coma, and died comatose about 11 A. M., January 29, 1891.

The autopsy was made at 4.30 P. M. the same day. The frame was large, the muscular condition good, and the adipose layer considerable. The dura mater was rather thicker than the average and more adherent to the skull, but there was no trace of pachymeningitis anywhere within the skull. The sinuses were normal. The convolutions were flattened, especially over the anterior lobes. The anterior half of the left hemisphere was larger than that of the right hemisphere. A section made through the middle of the left frontal lobe passed through a tumor, two inches in longitudinal diameter and an inch and three quarters in a transverse diameter, with a broken-down center. The anterior portion of this growth was firmer than the brain substance, and was grayish-pink in color, with a few small hæmorrhagic spots. This mass reached to within two inches of the anterior extremity of the hemisphere.

A vertical incision made from the lower extremity of the fissure of Rolando, and cutting the longitudinal fissure two inches and a half in front of the fissure of Rolando, passed behind the tumor.

The tumor involved the corpus callosum and protruded downward from the roof of the left lateral ventricle.

The heart was normal. The right lung was normal. The left lung contained a few fibrous nodules in the lower lobe. In the right iliac region there were several old peritoneal adhesions between the omentum, cæcum, vermiform appendix, and the abdominal wall. The spleen was normal. The liver was normal. The capsule of the left kidney was adherent, and its surface a little roughened by fine irregular scars.

A careful microscopical examination of the tumor proved it to be a gliosarcoma.

**Actæa Racemosa.**—"The tincture of cimicifuga, or actæa racemosa, combined with small doses of iodide of potassium, is very effectual in acute rheumatism and sciatica. It is rapidly absorbed into the blood, depressing both the force and frequency of the pulse. Rheumatism in the hands and wrists seems especially to yield to the action of this drug when many others fail."—*British and Colonial Druggist.*

## APPENDICITIS.\*

BY W. H. LINK, M. A., M. D.,  
PETERSBURG, IND.

THERE is hardly a doctor in Indiana of ten years' practice but has a private grave-yard in which are buried one or more victims of appendicitis. Most, if not all, of these unfortunates might have been restored to health and usefulness had the natural history of the disease been as well understood as it is to-day. Many of them perished with a different diagnosis accounting for the "inscrutable decrees of an all-wise Providence." "Bilious colic," no doubt, carried some away. Some were euphemistically removed by "obstruction of the bowels." Others went by the broad highway of gastro-enteritis. A few were swept into the river by the twin forces "typhlitis and perityphlitis." While many, very many, found in "idiopathic peritonitis" their *facile descensus Averno*.

These grave-yards, though not filling so rapidly as in times not very remote, still occasionally make room for another tenant. Melancholy as the facts just stated may be, let us remember that they constitute only the obverse side of the shield. We now know that these cases do not necessarily die. That they did heretofore die was due to a wrong conception of the disease, to baneful therapy, and an utter failure to grasp the surgical aspects of the case. The patient was first, last, and always stupefied with opium. It was "the sheet anchor." He was next beslimed with poultices from one weary day to another, till patient and nurse were alike exhausted. Now and then eminent counsel was called in, and, because he knew not what else to do, the poultice was replaced by a blister. Occasionally, when the obstipation became very marked, large enemata were ordered. The exhausting effects of septicæmia and peritonitis were combated with quinine, milk, and whisky. If, perchance, the pus was kind enough to make its way to the outer abdominal wall, some one, a little bolder than the others, incised the "boil" and the patient got well. This, I think, is a fair picture of past treatment. It is not yet altogether past.

The first and greatest advance made in this disease was in a better knowledge of its pathology. So long as typhlitis and perityphlitis or paratyphlitis were the nearest approach to a correct understanding of the condition, just so long was treatment uncertain and shadowy. We now know that a vast majority of the inflammatory troubles located in the ileo-cæcal region are, primarily, due to inflammation, ulceration, or perforation of the appendix vermiformis. We have learned that the question of therapy or surgery depends upon the advance made in the general progress of the case from a simple catarrhal or adhesive inflammation to a gangrenous perforation. Unfortunately, we are not yet advanced far enough in our diagnostic resources to determine with positive certainty the exact status of a case from the rational symptoms or physical signs. There are no pathognomonic symptoms, no invariable or infallible physical re-

actions or conditions, that, like guide-boards, point both forward and backward, marking the exact distance alike from the inception and the end. But while both diagnosis and prognosis are only a balancing of probabilities, the indications for a given line of treatment, founded either on an enlightened experience or scientific research, are unequivocal. Locking up the bowels with opium is supreme folly, for they are already locked in a vast majority of cases by the paralysis of distention and the obtunded sensibility induced by disease. But opium does not only lock up the bowels. The secretions of the entire alimentary canal are deranged, and some of the emunctories in other parts of the system fail in their activities under the influence of this baleful drug. Should the trouble be due to the presence or contact of irritating accumulations, the effect of opium is to increase rather than diminish the underlying causes. My own experience and that of others teaches me that most frequently the condition under consideration is due to traumatism from without, or infections and traumatism from within—those from without acting acutely in the form of blows, falls, and strains; those from within, either acutely or in a chronic manner, as foreign bodies, hardened feces, improper food, or the invasion of pyogenic bacteria which find a culture medium in accumulations of necrotic material due to abundant secretion excited by some local irritant, decomposition being favored by abnormal retention. By locking up the bowels with opium this condition is not only maintained *in statu quo*, but, being an active, not a passive one, the destructive processes are hastened. At the same time, the pain being subdued, neither patient nor physician has any means by which the downward progress of the case can be measured until often a septic peritonitis appears and the patient is beyond the reach of help.

In such cases the indications are certainly plain: To get rid of irritating material. To place the absorbing and digesting powers of the peritonæum at the best advantage. To lessen inflammation by depleting the local engorgement. To sweep away bacteria and their poisoning ptomaines in a copious exudation of fluid from the capillaries of the bowel. Every day such a line of treatment is the salvation of the patient who submits to a section for the removal of a pus-tube or an ovarian abscess. If it works wonders in these pelvic troubles, why not in appendicitis? This lesion produces death pretty much in the same way that a leaking pus-tube does. The line of treatment good for one ought to answer equally well for the other. Instead of giving opium and applying poultices, the indications are far better met by a full dose of sulphate of magnesium every hour till free watery discharges occur. Then absolute rest in bed and a strictly fluid diet. To illustrate the application of the foregoing principles, I wish to report the following cases coming under my care within the last year:

CASE I.—Young man, twenty-four years old, printer by trade, perfectly healthy heretofore, family history good (except that his father died of appendicitis under the old opium treatment), came into my office saying that he had a "soreness in his side" which gave him great pain, and which had been troubling him for the last twenty-four hours. Temperature, 102°; pulse, 100, and of that quick, jerky character noticeable

\* Read before the Mississippi Valley Medical Association at its seventeenth annual meeting.

in any trouble involving the abdominal viscera. Physical examination showed marked resistance over right ileo-cæcal region, with great tenderness on palpation. Pressure with the finger-tip at the McBurney point elicited prompt remonstrance. He was ordered to bed, forbidden anything but fluid nourishment, and put upon the following prescription:

℞ Magnesiæ sulphatis . . . . . ℥j.

℞. Sig.: Take one drachm every hour till free catharsis follows.

Next day his pain had disappeared, soreness and resistance diminished, fever abated, and pulse improved. His general improvement continued, until in a week he was apparently as well as ever, which condition he has maintained ever since, or almost a year.

CASE II.—Boy, sixteen years old, brought to the office by his father. Had been complaining of pain in his side while going to school for the previous three days. The boy, being very stoical in disposition, would not give up till the pain became so agonizing that he could endure it no longer. When he was first seen his features were pinched and drawn in a manner that expressed great suffering. He was bent over toward the right, and walked in a way to shield himself from sudden jars or movements. Tongue coated, bowels constipated, anorexia, fever, and the peculiar abdominal pulse as in the previous case. Physical examination showed very great tenderness in ileo-cæcal region, marked rigidity of the abdominal muscles, and the McBurney point easily demonstrated. Prescribed rest, fluid diet, and—

℞ Hydrarg. submur. . . . . gr. x.

℞. Sig.: To be taken at once, and followed in five hours by one drachm of sulphate of magnesium. Take in small amount of water, and repeat every hour till free watery dejections occur.

By next morning there was relief from pain and marked decrease in the abdominal tenderness and resistance. Improvement continued, so that in four days he was able to leave the bed, and in a week was apparently as well as usual. He has had perfect health since, or for about six months.

CASE III.—B. Y., young man, twenty-seven years old. Family history good; previous health good, except some trouble of late from constipation. Came in for advice in regard to "a lump in his side and a general bad feeling." Tongue coated; temperature, 102.5°; pulse, 105, and of that quick, jerky character as in the cases before described. In the ileo-cæcal region there was a large fusiform swelling. Over and around it there were well-marked abdominal resistance and tenderness on pressure. Pain was most easily demonstrated with the finger-tips at the McBurney point. He complained of pain down the inner and back part of the thigh of the affected side. He kept the right leg and thigh slightly flexed when lying on his back. About a week before applying for relief he was attacked with severe colicky pains radiating from the right side. After this, and about three days before I first saw him, he noticed the tumor in his side. Since then he had suffered so much from pain and soreness in his side and back that he could not turn over in bed without great suffering. The tumor itself was tense and elastic, but at no time could anything like fluctuation be obtained, and both œdema and redness were absent. Ordered him to bed, and forbid any but liquid nourishment. Prescribed—

℞ Magnesiæ sulphatis . . . . . ℥viij;

Acidi sulphurici aromatici . . . . . ℥jss;

Aquæ . . . . . q. s. ad ℥viij.

M. Sig.: One ounce every hour till all is taken.

He took the entire amount before noticing any effect. He then passed a large number of copious stools, completely emptying the gut. Next morning felt better, but there was no improvement in general symptoms, except that the temperature

had fallen to 100°. No change for four days, when tongue became more heavily coated and bowels ceased to move with regularity. Ordered—

℞ Hydrarg. submur. . . . . gr. xx.

Ft. chart. no. ij.

℞. Sig.: One every two hours, and after five hours give one drachm of sulphate of magnesium every hour till three doses are taken.

Free catharsis followed. After the effects of the calomel had disappeared the only improvement noticeable was in his ability to take nourishment. Considering his condition such that further medication was uncalled for, I advised a resort to surgery. Dr. Byers, Dr. Lamar, and Dr. Duncan then saw him, and, concurring in the diagnosis, advised an operation. At the request of himself and friends surgical interference was postponed till next day, in order that we might have daylight in which to do our work. In the mean time he had grown more restless, his temperature had risen to 103°, and his pulse gone up ten beats. The soreness was greater, and he thought he could feel a throbbing. Just after midnight he sent for me in great haste, saying it had burst inside, he thought. When I reached his bedside I found some diminution of the swelling; temperature, 98.5°; pulse, 85, and stronger. When we visited him the next morning his improvement was still noticeable, and operation was indefinitely postponed. His temperature continued to go above normal in the evening for three days, when both pulse and temperature remained normal. The swelling and tenderness gradually disappeared, till in fifteen days from the time I put him in bed he was able to walk about the house. After that his improvement continued so rapidly that in ten days more he was able to go to work. Four months afterward I examined him carefully, and could elicit neither swelling, tenderness, nor abdominal resistance. He is seemingly in perfect health, though I fear a recurrence.

CASE IV.—A. J. S., man, forty-six years old, farmer, always strong and healthy, came into the office with a soreness in his side and wanted medicine for relief. He had suffered for more than a week from severe colicky pains radiating from the right side, with great tenderness on pressure at ileo-cæcal region. Riding horseback or in buggy or wagon increased the pain and soreness. Tongue coated, bowels constipated, fever, rapid jerky pulse, abdominal resistance on palpation, McBurney point easily found. Ordered him to go home and go to bed; to take only fluid nourishment. Prescribed, as usual—

℞ Hydrarg. submur. . . . . gr. x.

℞. Sig.: Take at bed-time, and follow in the morning by one drachm of sulphate of magnesium every hour till the bowels move freely.

After catharsis he felt better. The next day, after being purged, he felt so much better that he got up and went to work. He has been working at intervals since, but when he "lets his bowels clog up he has pain and his side cakes." Salts give prompt relief, but some tenderness remains. Carries his hand in his pocket with the palm pressed against his abdomen over the site of the appendix, when riding or walking, to guard against sudden movements. He will not go to bed or keep quiet, but goes about his work. Any severe exercise brings on an exacerbation of his symptoms. I fear perforation with resulting peritonitis, but my patient will take medicine much more readily than he will take advice.

The foregoing represents my own experience with the saline treatment, and my own views founded on that experience and on what I have been able to glean from the experience of others. As late as four years ago physicians, in my part of the world at least, had just begun to see the

light on the mountain-tops. Before that period—typhlitis, opium, poultices! These were the nearest we ever got to the truth. Since then Morton, Sands, the Prices (Mor-decai and Joseph), McBurney, and others, have let in a flood of light; and prompt surgical treatment saves from an untimely death many an unhappy sufferer who, under the old *régime*, would have been removed with certainty if not with dispatch. Though surgery has responded to advanced knowledge, the old opium Man of the Sea has his legs still entwined about many a professional neck, and diagnosis is often obscured, prognosis made uncertain, and timely relief rendered impossible by his stupefying influence. The patient sleeps, and so does his medical attendant.

It was my misfortune to treat one patient under the old opium, poultice, do-nothing plan. He died from a septic peritonitis about as promptly as if he had been knocked on the head with a club. Observation in the practice of my friends has shown me two other cases. One of them died from idiopathic peritonitis, the other of shock from a section deferred for months till he was moribund. From the foregoing principles and facts I would beg leave to offer the following conclusions:

In the commencement of an attack give salines often and liberally till the gut is completely emptied. Advise perfect rest in bed. Forbid any but liquid nourishment. If pain is severe, apply counter-irritation and dry heat locally till salines act.

If the patient improves, wait. If the pulse grows worse, if the temperature rises, if pain increases, if tumefaction becomes larger, if tenderness becomes more marked, *operate*. At no time give morphine, but consider an increase of pain sufficient to demand relief by opium an imperative, unequivocal, and emphatic indication for surgical interference.

## THE TREATMENT OF LARYNGEAL TUBERCULOSIS WITH LACTIC ACID LOCALLY.

By CHARLES R. WEED, M. D.,

UTICA, N. Y.

It is not necessary to repeat here the many details of general therapeutics, dietetics, or hygiene which have been so fully discussed in the past ten years by writers upon tuberculous disease, and I shall confine myself simply to the local treatment as used in three typical cases, trusting that my experience may add to the future a remedy to combat the inroads of tuberculous laryngitis.

In presenting these cases I have taken care to observe closely each condition, and particularly to assure myself that the disease germ or tubercle bacillus was present in each, confirmed by microscopic investigation. I do not claim originality in the use of lactic acid, but, after reading that Krause, of Berlin, had been most successful in this form of local treatment, claiming, and no doubt justly, the cure of a small number of cases, in an exhaustive paper read before the Laryngological Subsection of the Fifty-ninth Meeting of the German Naturalists and Physicians, at Ber-

lin, September 21, 1886, I determined to try it, and the efficacy of his suggestions is shown in the following cases:

CASE I.—I. M., German, aged thirty-eight years, occupation furniture finisher, called on me November 2, 1887, and gave the following history: About two years previous he had noticed that his general health was failing, and, being troubled with a bad cough, consulted a physician, who diagnosed his trouble to be phthisis. He was put upon treatment, but the disease progressed until in June, 1886, when his throat began to trouble him. He drifted from one practitioner to another, but could get no relief. At last he was advised by friends to consult me (I being a new-comer here), as he was unable to either eat or drink without great distress. This man was terribly emaciated; his face was anxious; breathing hurried; temperature, 101°; pulse, 90 and weak; voice lost; in fact, every symptom betokened the "beginning of the end." Considering the case hopeless, I gave him no encouragement, but said I would do what I could to relieve the laryngeal pain and the dyspnoea.

Examination laryngoscopically revealed as follows: Membranes pale; ventricular bands and space infiltrated; submucous membranes covering the arytaenoids and ary-epiglottic folds tumefied; vocal cords but slightly visible, the edge of the left one having the characteristic ulceration of tuberculous disease. I proceeded to cleanse the parts carefully with a mild alkaline spray; then applied, with the cotton carrier, a six-per-cent. solution of cocaine thoroughly; after this a sixty-per-cent. solution of lactic acid to every visible diseased surface of the larynx. Though weak, he stood the application well, and after giving him general instruction as to his treatment at home—sprays, medication, etc.—he left, to call again two days after.

This patient improved wonderfully; in two weeks he was able to eat and drink without much discomfort, and at the end of three months had gained several pounds in weight. The treatment was kept up at short intervals for a period of eighteen months, and a gain of sixteen pounds resulted; the voice was slightly improved, now reaching to a hoarse whisper. As he considered himself on the road to recovery, I saw less and less of him, and he left here in June, 1889, for the West, and I lost track of him; but a lease of life of two years nearly was a result to be satisfied with, particularly after the prognosis made in his case.

CASE II.—On November 26, 1890, I was called in consultation by Dr. Nicholson, of Madison, N. Y., to see a Mrs. B., aged forty-one; family history bad; cancerous disease, both parents; had been ailing for three years, and lately had emaciated rapidly; weight at present time, eighty pounds; menstruates regularly, no pain. The lung sounds were negative, which coincided with the opinion of other physicians who had examined her prior to my being called. In September, 1890, she lost her voice, and now speaks in whispers; she complains of pain over and in the larynx; temperature, 100°; pulse, 88; appetite good, but can not gratify it, owing to the dysphagia, regurgitation of fluids, and constant cough; sleep disturbed, and she feels very weak and discouraged.

Laryngoscopic examination shows the characteristic lesions of tuberculous disease, but not so far advanced as in Case I. The disease here being primary, I at once decided to treat the case with the lactic acid, and, following the routine above given, made the application, and with direction to the attending physician left, requesting him to acquaint me from time to time of the patient's condition.

Two months after I was sent for to see this patient and was surprised at her improvement. Deglutition was resumed and without pain; the swelling and infiltration in the larynx had subsided and the ulcerations healed (originally there were sev-

eral small tuberculous ulcers on the epiglottis); she could sleep the night through, and the cough had decreased so that the irritation from that source was remedied; I gave a few suggestions, curtailing the acid in strength and frequency, also modifying the sprays which she was using.

The last report from this patient is that she is still improving, and that the throat gives her no discomfort. Her general health is better, and there is slight increase in weight; the voice continues about the same; at times she thinks she notices a slight increase in tone.

CASE III.—Miss E. D., aged eighteen years, sent by Dr. Shumway, of Utica, N. Y., September 2, 1891, with history of phthisis, which was confirmed on examination. For the past two weeks she had complained of inability to swallow either liquids or solids without great pain; voice lost; is very thin, only weighing seventy-two pounds; menstrual function normal. This was simply a question of immediate relief or slow starvation, and for this reason I had been consulted. Examination showed a great amount of infiltration, with tumefaction of the membranes, and space nearly closed; I also noticed that the ulceration in this case coalesced, and part of the cartilage was destroyed. I was obliged to scarify to relieve the œdema present, and then followed the routine employed before, but only using in this case a twenty-per-cent. solution of the acid. The patient did not stand the application very well, there being so much pain present, which the cocaine did not control as well as in Cases I and II; still, she promised to call the day following, which she did, and I increased the acid to a thirty-per-cent. solution; this treatment was continued tri-weekly, and she now experiences no pain upon either eating or drinking. This case I have little hopes of, as the disease in the lungs is so far advanced, but I cite it with the other two to prove the value of relief obtained from the use of the acid over every other form of local medication.

Other cases under treatment I do not consider myself justified in presenting, as time sufficient to prove results has not transpired, but all show improvement from their original conditions when first seen by me.

In conclusion, I will say that the treatment that these patients had been subjected to prior to my seeing them had consisted of about all the local remedies from menthol to iodoform, and the nitrate of silver—so strongly lauded by the late Professor Horace Green, of New York—in strength varying from a twenty to a sixty per cent. solution, but without *relieving* the diseased conditions. Have we then in lactic acid the remedy *par excellence* in this disease? I trust so, and hope that others of my medical brethren may be led to use it, and, like myself, give to medical literature the results they obtain.

226 GENESEE STREET.

## A CASE OF UMBILICAL HÆMORRHAGE.

BY R. H. MONTGOMERY, M. D.,  
CLEVELAND, OHIO.

On the 24th of December, 1890, I was called to see Mrs. E. She had been married eleven years; had had one child eight years ago. No miscarriages. She was a large, well-nourished woman, and had always enjoyed excellent health. She was now eight months pregnant. On the preceding day she had taken a laxative. I was called to check a violent diarrhœa which had been in operation during the night and forenoon. She had considerable griping, but no uterine pains or uterine

hæmorrhage. No vaginal examination was made. Morphine was prescribed and in six hours I called again. She was then having labor pains, and the os was dilated to the size of a half-dollar. It was a face presentation. Labor progressed normally, and in four hours she gave birth to a male child weighing three pounds and a half. It was weak, poorly nourished, and had a pronounced "old-man" appearance. The possibility of hereditary syphilis was entirely eliminated by information from a thoroughly reliable source.

The child was enveloped in cotton and intrusted to a competent nurse. It did well. On the fourth day the cord separated and the umbilicus assumed the usual appearance.

By the eighth day it had gained considerable strength, and its battle for life seemed to have been won. On the afternoon of this day the nurse found the abdominal band stained with blood from the navel. When I called I ordered alum to be applied if there was any more bleeding. I was called in three or four hours, there having been a return of the hæmorrhage which alum and other astringents had failed to control.

I poured brandy over the navel, which immediately stopped the bleeding, and it did not return for six hours.

Upon its reappearance, brandy was again tried, but without avail. Pledgets of absorbent cotton, saturated with Monsel's solution, were then pressed into the umbilicus and held there. This promised good results.

Dr. A. C. Wilson, of Youngstown, was called in consultation. It was decided to pack the navel with the saturated cotton and arrange a graduated compress over this, held in place by an elastic bandage encircling the abdomen.

For eight hours no hæmorrhage was visible, and the anxiety of the family and myself had somewhat abated. At the end of this time, to our dismay, blood was found oozing from beneath the bandage. A fresh dressing was applied, but to no purpose.

I then placed my thumb upon the navel, and, with my fingers over the lumbar vertebra, the navel could be compressed against the bodies of the vertebrae, controlling the bleeding. The father and myself alternately compressed the umbilicus in this way for several hours, but eventually the blood would well up around the compressing finger with every movement of the now restless and almost transparent babe. Finally no degree of compression we were able to make would control the hæmorrhage. Our efforts were as fruitless as those of Sisyphus.

At this juncture I obtained the consent of the family to transfix the umbilicus with needles. The needles were introduced at right angles to each other, going deeply into the tissues and crossing each other beneath the umbilical depression. The ends of the needles were approximated and a figure-of-eight ligature applied. This controlled the bleeding at once. After forty-eight hours the needles were removed and, happily, there was no return of the hæmorrhage.

The child rapidly gained flesh and strength, and now, at the age of eleven months, is a fine, healthy baby, never having been sick since this early experience.

Fortunately, these cases are rare, occurring only once in about five thousand births. The case reported in the *Journal* for October 31st by Dr. Wagoner is a very interesting one. The method of treatment which proved successful in his hands should not be lost sight of, as the high percentage (eighty-three per cent.) of deaths in these cases shows how inefficient treatment has been, and the success of this treatment, after the usual remedial measures had been tried and found wanting, bears testimony to its efficiency.

842 LOGAN AVENUE.

A CASE OF BASILAR MENINGITIS  
DEVELOPING FIVE WEEKS AFTER AN INJURY TO THE HEAD.

By EDMUND Y. BURROUGH, M. D.,

SURGEON, RED STAR STEAMSHIP LINE.

On the morning of Tuesday, the 22d of September, I was called to see H. C. B., a seaman, aged twenty three years, a native of Denmark. He was a robust, well-developed man. I found him in his berth in the fore-castle. He complained of feeling alternately hot and cold. His bowels had not moved for four days. He had headache; his pulse was 120 in the minute. I gave him four compound cathartic pills and twelve grains of quinine, to be taken in divided doses during the day. At midnight of the same day I was again called to see him. His messmates told me that he was "out of his head," and that they had great difficulty in keeping him in his berth.

He replied to my questions in a rational manner; said that his bowels had moved three times since morning, and quite freely each time, but that his headache was no better. I gave him ten grains of antipyrine and left three five-grain powders to be taken an hour apart. On Wednesday, at 9 A. M., I saw him again, and found that he had passed his urine and feces in bed. At this time he was comatose, his eyes wandering about restlessly, and he took no notice of the hand passed before his eyes. The conjunctival reflex was absent; the patellar reflex was present in both legs; the ankle clonus was present, and equally good in both ankles. No strabismus was apparent. The point of a pen-knife drawn across the soles of his feet elicited no response. On pressure there was a slight gurgling sound in the right iliac region. On the abdomen were some spots resembling those seen in cases of typhoid fever, but they disappeared on pressure. He was given one tenth of a grain of calomel every hour for ten hours, and an ice-bag was applied to his head.

In the afternoon of the same day he took a small quantity of milk and beef-tea, this being the first nourishment he could be induced to take. At 7 P. M. his temperature was 99.9°, pulse 120, and he was in a profuse perspiration. The spots visible on the abdomen in the morning had disappeared.

At 10 P. M. his temperature was 101.9°, pulse 140. Strabismus was now noticed for the first time, as well as paralysis of the alæ of the nose. Opisthotonos was well marked. The patient now lay with his head turned toward the left side, and there was constant twitching of the right arm and leg.

At 8 A. M. on the 24th his pulse was 120 and very weak; temperature, 101.8°; respiration, 48 in a minute. At 9.15 he died.

The interest in this case lies in the fact that five weeks before the symptoms of meningitis manifested themselves the patient was, with others, hauling on a watch-tackle when the hook of the distant block broke off and the block, flying back, struck him on the left parietal region with considerable violence. Although the skin was scarcely broken, he appeared to suffer great pain at the time, but after a few minutes seemed relieved and resumed his work. He did not "lay up" on account of the blow, or, as far as I know, did he suffer any further discomfort from it until the beginning of his fatal illness, which was undoubtedly the result of the accident.

The International Dermatological Congress of 1892 will meet in Vienna, on September 5th to 10th. Dr. Prince A. Morrow has been appointed secretary of the Congress for North America.

THE  
NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JANUARY 9, 1892

THE PHYSIOLOGY OF TEARS.

This subject is considered in a bright and interesting paper recently published in the *Asclepiad*. Fear, grief, and joy, to say nothing of pathos and anger, bring tears to the eyes. They are said to come from the heart; and this is true, for no one ever reasoned himself into weeping without a first appeal through the imagination to some emotion. Tears are the natural outlet of emotional tension. They are the result of a storm in the central nervous system, giving rise to changes in the vascular terminals of the tear-secreting glands. These changes induce profuse excretion of water, and weeping results. In a mild degree some excretion is always in process, to bathe the eye and clear it of foreign matters. The controlling center is at a distance, though the secretion may be kept up by the small trace of saline substance that is present in the tears themselves. The lacrymal glands lie between the nervous center and the mucous surface of the eyeball. Tears afford a good illustration of the way in which nervous fibers are capable of conveying to a secreting organ exciting impulses from both sides of a gland lying in their course. Afferent and efferent communications bring about a similar result. Internal nervous vibrations and external excitation or reflex action cause a flow of tears. In both instances the exciting impulse is a vibration. Niobe, "all tears," and the unfortunate pedestrian with a minute particle of steel from the rail of an elevated road in his eye, are unwilling exponents of a similar process. They weep the same kind of briny fluid, in exactly the same way, though from widely different causes. Imagination is at times sufficient to excite the nervous system into the production of tears, without external aid or reflex. Writers and readers of good fiction weep over it alike, and the actor loses himself so entirely in the exigencies of dramatic art that he sheds real tears and the audience shed tears with him. Of a truth, the man who never weeps has a hard heart, and the quality of his intellect may also be questioned.

Emotion, then, affection, grief, anxiety, incite to tears, not pain or discomfort. The pangs of maternity are tearless, though the influence of ether or chloroform may cause some emotional dream that results in weeping. In the earlier days of surgery patients might scream and utter such pitiful cries as to sicken the by-standers, might even faint with pain, yet there were seldom any tears. These, being pure waves of emotion and a relief to the heart, are almost powerless to mitigate pain. Perhaps one who weeps from pain does so from unconscious though selfish pity—in other words, from emotion.

For the tearful, change of scene, mental diversion, and outdoor life are the best remedies. The author quoted objects to

alcohol as fearfully injurious. It disturbs and unbalances the nervous system, keeps up a mandlin and pitiful sentimentality, and sustains the evil. Alcohol is the mother of sorrow. An opiate, however, prescribed at night, soothes and controls and really disciplines rebellious nerve centers. Sleep cures tears. And so does Time, the restorer. Persons subjected to many and repeated griefs forget how to weep, and the old as compared to the young are almost tearless. Tears have their value in the life of humanity, not as tears but as signs. They show that grief centers are being relieved of their sensibility, and that the nervous organization is learning how to bear up against sorrow.

#### TETANUS NEONATORUM.

THE infectious nature of tetanus was for a long time suspected, and the truth of that belief is now conclusively proved. Nicolaier eight years ago found in superficial soil a bacillus which by inoculation produced tetanus in animals. Not long after, a germ of similar appearance and life history was found by Rosenbach in the secretions from a wound of a patient suffering from tetanus. The chain of evidence was not completed until recently, when Kitasato, a student in Koch's laboratory, succeeded in isolating the germ and produced tetanus by inoculation of its pure cultures. There is still doubt as to whether this germ is the only one which may produce the disease. Examination of the surface soil of various countries shows that the bacillus of Nicolaier is very wide spread, being more common in that from tropical regions. This agrees with clinical experience, for the disease, as a rule, is much more common in hot than in cold countries. Experiments show that while the digestive fluids have not the power either to kill or alter the germ, a dose vastly greater than that required to produce death by inoculation can be taken into the stomach with impunity. This is also in accordance with clinical experience, for the disease develops in connection with an open wound or an unhealed umbilicus. The evidence is strong that the disease is at first local in character, and there is ground for the belief that it may be prevented by early treatment at the point of inoculation. There is certainly much to be expected from cleanliness and antisepsis as prophylactics, and this, again, is in accord with practical experience.

The fact that the disease is prevalent in certain localities, causing the death of a large proportion of new-born children, and attacking nearly every surgical patient, is strong evidence of its infectious nature. It has for years been a scourge of Iceland, contrary to the usual rule that it is more prevalent in warm climates. The *Lancet* for July 15, 1891, reports that it is also alarmingly frequent in St. Kilda, one of the Hebrides Islands. The disease has for several years been vastly on the increase in spite of the amelioration in the comfort and social condition of the population. The mortality has become so alarming that an agent has been sent to confer with the medical authorities of Glasgow. The symptoms develop within a week after birth, the most marked being tetanic convulsions, which increase in severity until the child dies. The disease runs its course in

about twenty-four hours, and is always fatal. Of the numerous hypotheses regarding the aetiology of tetanus, that of its infectious nature is the only one which satisfactorily explains the condition existing at St. Kilda and other isolated communities.

### MINOR PARAGRAPHS.

#### RELAPSE IN SCARLET FEVER.

It was believed by the older authors that relapse in scarlet fever does not occur. As opposed to recurrence, true relapse is certainly rare, but that it does sometimes occur can not now be doubted. It would seem to be analogous to the relapse of typhoid fever. Hensch believes that, though less common than in typhoid, actual relapse does occur. After the patient has been free from fever several days or even weeks the temperature suddenly rises, the rash again appears, sometimes over a portion of the body only, and the patient passes through a typical course followed by desquamation. In many cases the course of the disease in the relapse is irregular. However mild the symptoms may be, the relapse must not be regarded as less important than the primary attack. In the *Edinburgh Medical Journal* for October, 1891, Mr. Boddie reports two undoubted cases of relapse. The first patient, after passing through an attack of scarlet fever of moderate severity, followed by desquamation and albuminuria, had apparently made a perfect recovery. On the thirty-seventh day, following exposure to cold and wet, the temperature suddenly rose to 103° F., a rash appeared, and he passed through another typical attack of scarlet fever. Desquamation was more profuse than after the first attack. In the second case the relapse occurred on the twenty-seventh day. The attack continued about five days and was not as severe as the first illness. The second desquamation began on the thirty-fifth day. It was partial and was quite over in a week.

#### A STUMBLING-BLOCK TO MEDICAL WRITERS.

Is there ever to be an end of the pranks played by the little Latin word *os*—whether meaning bone or mouth—in medical writings? It is not many months since we called attention to an instance in which the *Centralblatt für Gynäkologie* used the expression "ossis uteri," and now we find the *Lancet* heading one of the editorial annotations in its issue for December 19th A Case of Defecation *per Orem*!

#### ITEMS, ETC.

**The Alumni Association of the College of Physicians and Surgeons** will give a dinner on Saturday, the 16th inst., in honor of the consummation of the active union recently established between their *Alma Mater* and Columbia College. Addresses are expected from President Low, of Columbia College; Dr. J. W. McLane, Dean of the Medical School; Dr. W. H. Draper, of the medical faculty; Mr. J. H. Choate, Mr. F. Hopkinson Smith, and others.

**The Harlem Medical Association.**—At the meeting held on the 6th inst. the order of business was a paper by Dr. T. H. Manley, on The Pathology and Treatment of Diseases of the Hip, Knee, and Ankle Joints.

**The New York Academy of Medicine, Section in General Surgery.**—The meeting to be held on Monday, the 11th inst., will be devoted to a consideration of the subject of Surgery of the Intestinal Tract. Specimens illustrating intestinal tumors, sutures, anastomosis, etc., will be exhibited; Dr. R. F. Weir will present a patient in whom the ileum was transplanted to the sigmoid flexure; Dr. R. Abbe will read the re-

of his personal work in this field, and the subject will be discussed at length by Dr. J. A. Wyeth, Dr. B. F. Curtis, Dr. W. T. Bull, the chairman, and others.

**Medical Attendance in the Jury-room.**—"The sanctity of a jury-room appears to be so well guarded that, even in case of sudden sickness, a physician may not enter except after due process of law. In the Foss will case, tried recently in Boston, the jury were deliberating, when, late in the evening, one of them was suddenly attacked with what proved to be a stroke of apoplexy. The officer in charge notified the deputy sheriff, who, not having authority to let any one into the jury-room, drove across the city and informed the sheriff, but even this official was not high enough to act, and another expedition started in search of the judge. As the latter happened to be at home, the requisite order was obtained to summon a doctor."—*Boston Medical and Surgical Journal*.

**Marine-Hospital Service.**—*Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the three weeks ending December 19, 1891:*

- BAILHACHE, P. H., Surgeon. Detailed as chairman of Board for Physical Examination of Officer, Revenue Marine Service. December 17, 1891.
- STONER, G. W., Surgeon. Granted leave of absence for twenty-one days. December 16, 1891.
- CARTER, H. R., Passed Assistant Surgeon. To proceed to South Atlantic Quarantine for temporary duty. December 10, 1891.
- BANKS, C. E., Passed Assistant Surgeon. To inspect unseviceable property at Marine Hospital, Baltimore, Md. December 10, 1891.
- DEVAN, S. C., Passed Assistant Surgeon. To proceed to Montreal, Canada, on special duty. November 30, 1891.
- PETTUS, W. J., Passed Assistant Surgeon. To report in person to the Supervising Surgeon-General, December 3, 1891. To proceed to New Berne, N. C., on special duty. December 12, 1891.
- GOODWIN, H. T., Passed Assistant Surgeon. Granted leave of absence for ten days. December 2, 1891.
- STONER, J. B., Assistant Surgeon. Granted leave of absence for seven days. December 18, 1891.
- CONDUCT, A. W., Assistant Surgeon. Granted leave of absence for seventeen days. November 30 and December 15, 1891.
- GUITÉRAS, G. M., Assistant Surgeon. Granted leave of absence for ten days. December 15, 1891.
- STIMPSON, W. G., Assistant Surgeon. Granted leave of absence for ten days. December 2, 1891.
- BROWN, B. W., Assistant Surgeon. Detailed as recorder of Board for Physical Examination of Officer, Revenue Marine Service. December 17, 1891.
- COFER, L. E., Assistant Surgeon. Granted leave of absence for fifteen days. December 15, 1891.

#### Society Meetings for the Coming Week:

**MONDAY, January 11th:** New York Academy of Medicine (Section in General Surgery); Lenox Medical and Surgical Society (private); New York Ophthalmological Society (private); New York Medicohistorical Society (private); New York Academy of Sciences (Section in Chemistry and Technology); Boston Society for Medical Improvement (annual); Gynecological Society of Boston; Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private); Baltimore Medical Association.

**TUESDAY, January 12th:** New York Medical Union (private); Kings County Medical Association; Medical Societies of the Counties of Chautauqua (semi-annual), Chenango (annual), Clinton (annual—Plattsburgh), Erie (annual—Buffalo), Genesee (semi-annual—Batavia), Greene (quarterly), Jefferson (annual—Watertown), Livingston (semi-annual), Madison (semi-annual), Oneida (semi-annual—Rome), Onondaga (semi-annual—Syracuse), Ontario (quarterly), Oswego (semi-annual—Oswego), St. Lawrence (annual), Schenectady (annual—Schenectady), Schuyler (annual), Steuben (semi-annual), Tioga (annual—Owego), Wayne (semi-annual), and Yates (semi-annual), N. Y.; Newark, N. J. (election), and Trenton (private), N. J., Medi-

cal Associations; Norfolk, Mass., District Medical Society (Hyde Park); Baltimore Gynecological and Obstetrical Society.

**WEDNESDAY, January 13th:** New York Surgical Society; New York Pathological Society; Metropolitan Medical Society (private); American Microscopical Society of the City of New York; Medical Societies of the Counties of Albany and Dutchess (annual—Poughkeepsie), N. Y.; Tri-States Medical Association (Port Jervis, N. Y.); Pittsfield, Mass., Medical Association (private); Hampshire (quarterly—Northampton) and Worcester, Mass. (Worcester), District Medical Societies; Bennington, Vt., County, and Hoosie, N. Y., Medical Society (annual—Arlington, Vt.); Philadelphia County Medical Society; Kansas City, Mo., Ophthalmological and Otolological Society.

**THURSDAY, January 14th:** New York Academy of Medicine (Section in Pediatrics); Society of Medical Jurisprudence and State Medicine; Brooklyn Pathological Society (annual, election); Medical Societies of the Counties of Cayuga, Fulton (annual—Johnstown), and Rensselaer (annual), N. Y.; South Boston, Mass., Medical Club (private); Pathological Society of Philadelphia.

**FRIDAY, January 15th:** New York Academy of Medicine (Section in Orthopedic Surgery); Baltimore Clinical Society; Chicago Gynecological Society.

**SATURDAY, January 16th:** Clinical Society of the New York Post graduate Medical School and Hospital.

## Letters to the Editor.

### DISAPPEARANCE OF SUGAR IN A CASE OF DIABETES MELLITUS.

AUGUSTA, ME., January 5, 1892.

To the Editor of the *New York Medical Journal*:

SIR: In the issue of the *New York Medical Journal* for January 2d J. Page Burwell, M. D., of Washington, D. C., reports a case of diabetes mellitus and its successful treatment. Having seen equally pleasing results follow very different treatment in a similar case, I am prompted to report the case.

On March 8, 1889, I was called to see Mrs. H., married, aged forty-eight. The patient complained of intense pruritus of the genitals, accompanied by considerable tumefaction, and an excoriated condition of the inner aspect of the thighs. There was great polyuria, frequent and painful micturition, followed by extreme distress, after the act, and lasting some minutes. She complained of severe headache, backache, and general malaise.

Upon examination of the patient, I found that she further complained of intense thirst, that the tongue was red and glazed, and the appetite deranged—at times excessive, at other times almost *nil*. There was also feebleness of vision, and an eczematous eruption upon different portions of the body. The *embonpoint* of the patient was very noticeable.

An examination of the urine gave a specific gravity of 1.056 with an acid reaction. Fehling's test showed a large amount of sugar.

The treatment was five-grain doses of iodide of potassium before each meal. One saline and chalybeate pill three times daily. A teaspoonful of Sprudel salts in a glass of water before breakfast each morning.

The diet consisted of gluten bread, milk, fish, and those vegetables allowable in this disease.

Under this treatment the sugar gradually disappeared, as determined by fortnightly tests of the urine, until a test made July 1, 1889, failed to show the slightest trace.

The patient returned to her normal weight in a few months, and is now apparently well. W. H. HARRIS, M. D.

## Proceedings of Societies.

### NEW YORK NEUROLOGICAL SOCIETY.

Meeting of December 1, 1891.

The President, Dr. L. C. GRAY, in the Chair.

#### Resection of Posterior Branches of Upper Three Cervical Nerves for Spasmodic Torticollis, with Report of a Case.—

Dr. CHARLES A. POWERS read a paper with this title. (Will be published.)

Dr. R. W. AMIDON thought that Dr. Powers had been too modest in that he had not called attention to the marked improvement in the patient's right arm. Before the operation this had been practically powerless, while now its functions were restored. The position of the head was now similar to that before the operation, but the spasm was now tonic instead of clonic, and therefore much more endurable. There was now no elevation of the chin, which was conclusive proof that none of the muscles originating or inserted in the occipital bone were now implicated. The elevation of the right shoulder was now much more marked and there was no doubt that the levator anguli scapulae entered largely into the production of the deformity. The speaker then went over the action and nerve supply of the muscles of the shoulder with the view of demonstrating that possibly the present condition might be brought about by this group, the nerves which had not been cut.

Dr. C. L. DANA thought that the muscles of the right side, which had been cut, had possibly entered into the production of the spasm, but that the nerve force was now distributed through fewer channels, and perhaps this was the reason that the spasm was now tonic. The question was at any rate of extreme interest, because heretofore there had been much skepticism as to the value of operation for wryneck. He thought that the experience of American observers was that operation on the spinal accessory had been uniformly fruitless, but the relief obtained where the upper cervical nerves were involved had given a more favorable showing. With better technique, perhaps more favorable results would come in the case of the spinal accessory. He did not doubt but that the condition under consideration was the result of a central nervous lesion. Why surgical treatment should cure he did not know, unless it was the result of the operation *per se*.

Dr. M. A. STARR had seen these cases treated by division of the spinal accessory. No improvement had followed. He had therefore hesitated to recommend such procedure. He thought it had yet to be demonstrated that the condition was one of cerebral origin, as there was nothing analogous to wryneck in the form of cerebral spasm of any other muscle. A patient had come to him last February with an extremely pronounced case of wryneck. This patient had noticed that pressure on the right side of the occiput high up would relieve the spasm. An apparatus was accordingly constructed which, being constantly worn, had enabled him at the onset of the spasm to bring the necessary pressure to the required spot by means of a system of levers worked by his arm. The speaker had that day seen the patient, and had found him apparently perfectly cured and able to leave off the apparatus. It was difficult to determine in these cases what muscles or set of muscles was implicated. The spasm was probably a complex act by a large number of muscles and usually reflex in character, induced by sensory irritation somewhere.

Dr. W. M. LESZYNSKY thought that there was a lack of such pathological knowledge of the disease as would indicate that there existed a central lesion. It was remarkable that so few

microscopical examinations had been so far made of nerves which had been resected. In the present case no explanation had been offered as to the cause of the arm symptom, and whether it was supposed to have borne any relation to the spasm in the neck. He had been interested in a few cases of spasmodic wryneck, and felt confident that the hypodermic injection of atropine had helped them. He had reported a case in which the spinal accessory was implicated, and he had felt that the benefit done was the result of the atropine. He thought that this measure should be energetically tried as part of a treatment by drugs before surgery was resorted to.

Dr. G. M. HAMMOND said that the general idea was that operations of this kind were not successful. The result in the present case seemed to relate more to the comfort of the patient than to benefit from a pathological standpoint. It might be easier for the patient to have a tonic instead of a clonic spasm, but the condition of wryneck remained.

Dr. J. M. MORRIS cited the history of a patient who had come to him with a well-marked case of spasmodic wryneck of long standing. Every effort had been made therapeutically. He had tried suspension. The sittings had numbered about five, each lasting about five or six minutes, the patient's toes being just free of or barely touching the floor. Improvement had been prompt and had continued to a cure, which had been maintained up to the last report.

The PRESIDENT had never seen any good results from operative work in these cases. While out of a large number operated upon for him by different surgeons temporary improvement had taken place in some, relapse had ultimately occurred. He had obtained more satisfactory results by deep injections of atropine than from any other form of treatment, though he had found the internal administration of belladonna effective. As to the permanency of the atropine benefit he could not speak, the patient having passed from observation. Temporary results were worthless for purposes of deduction, and relapses were probable at any time.

Dr. POWERS thought that the indications for operation must come from the physicians, surgeons being hardly justified in interfering until every other method of treatment had been tried. Promise of amelioration must be guardedly given. If the technique were perfected so as to cover the nerve supply to the muscles involved, he did not see why the spasm could not be stopped.

**Alleged Cerebral Tumor.**—Dr. LESZYNSKY showed a patient whom he had presented to the society three years ago; at that time the diagnosis had been made of cerebral tumor. The symptoms had then been frontal headache, vomiting, and double optic neuritis. Now this man was in perfect health, and since treatment had never lost a day's work from illness. There was atrophy in both optic nerves. Vision was in one eye,  $\frac{3}{80}$ ; in the other,  $\frac{2}{80}$ . There was no disturbance in the color field. The treatment during the acute stage had been by large doses of iodide of potassium, with leeches and cathartics when the inflammation was excessive. The speaker had been able to find only one case where autopsy had revealed localized basilar meningitis in the region of the optic chiasm.

### NEW YORK ACADEMY OF MEDICINE.

SECTION IN GENERAL SURGERY.

Meeting of November 9, 1891.

Dr. WILLIAM T. BULL in the Chair.

**The Pernicious Effect of Early Excision of the Knee Joint in Children.**—Dr. V. P. GIBNEY exhibited a number of patients for the purpose of illustrating this point. In all the

cases shown there was marked shortening, in some instances amounting to five inches, and the excisions had left sinuses and other sequelæ, which had called for treatment by osteotomies at the hands of the speaker when the patients had come under his care.

**The Fibula used to effect Union after Compound Fracture of the Tibia.**—Dr. B. F. CURTIS showed a patient who last June had caught his leg in the belt of a planing machine, the limb being forcibly carried against the pulley. The resulting injury had been compound fracture of the tibia and fibula and fracture of the femur. Three inches of the tibia had projected through the wound and union had taken place in the femur and in the fibula, but had failed in the tibia. When the speaker saw the patient first there had existed a considerable gap between the ununited fragments, the space being occupied by a granulating mass. He had found that any attempt at freshening the ends of the bone and using mechanical approximation would result in a total shortening of the leg of three inches. He had therefore cut down on the fibula and forced it through the soft parts into the gap between the tibia fragments, which had been previously freshened. The resulting union had given the patient a leg with only an inch and three quarters of shortening, much of which was due to the fracture of the femur. Union had taken place slowly, but was already sufficiently firm to enable the limb to support the man's weight. There had been no inflammatory action.

**Trephining for Traumatic Epilepsy.**—Dr. A. J. McCOSH presented a boy, seven years of age, who, on August 11, 1890, had fallen down stairs and had been found in a semi-comatose condition. He had remained in this state for some twenty-four hours at the hospital and could only be aroused with difficulty, lapsing immediately into unconsciousness. There had been no paralysis and no lesion of the scalp. On the third day the patient had been less stupid but extremely irritable. By the seventh day intelligence had been restored, but there had been partial paralysis of the left upper extremity and of the left side of the face, with twitchings over these areas, going on to convulsions limited to the left side. On the eighth day paralysis of the left upper and lower extremities had been complete and the patient had had several epileptic seizures commencing in the left arm and becoming general. The diagnosis had been that of pressure by clot on the motor center for the left arm, face, and leg in the posterior and anterior ascending convolutions. Operation had demonstrated the external surface of the skull as uninjured, but that there was a clot, which was followed backward, by use of the rongeur, from the original trephine opening, made three quarters of an inch in front of and about the middle of the Rolandic fissure. This clot was beneath the dura mater, which had appeared to be uninvolved. To fully expose and enucleate this clot, which was half an inch thick, had required an opening in the skull of two inches and a half in diameter. It had then been observed that at the posterior part of this opening there was a fissure running upward and backward, meeting at a sharp angle a second fissure running downward toward the ear through the squamous portion of the temporal bone. This triangular piece of bone being removed, a tear was seen in the dura mater an inch and a quarter long, with a quantity of broken-down brain substance beneath it. After thorough removal of clot and *débris* the scalp was sutured over a drainage-tube. Some slight movements had taken place in the paralyzed left arm as the boy had come from under the anæsthetic. In twenty-four hours movements had become pretty general over affected areas. In three weeks motion had been complete, and in six weeks they had been of normal strength. The patient had become perfectly well and had so remained. There was at present no inconvenience of any kind. The case

was one of brain irritation with destruction and with symptoms of both. The exact localization of the clot had been made from the symptoms alone.

Dr. R. H. M. DAWBARN cited a case in which he had trephined on the right side for left hemiplegia. The patient had complained of most pain on this side, but on the brain being exposed there had been no lesions to account for the compression symptoms. Post-mortem examination had revealed a large clot on the same side as the paralysis. This case he regarded as one in which there was no crossing of the motor fibers in the medulla. In future cases, while he would make his first trephine disc on the side indicated by physiological rules, he would then, if he failed to find cause for the symptoms, make his next attempt over the most recent external evidence of injury he could find.

Dr. J. D. BRYANT said that one of the special features of the cases mentioned was that trephining had been resorted to at all. Two cases had come under his observation within six months in which the trephine had been used when there had existed no scalp lesion, the operation being undertaken on account of the paresis and convulsive symptoms. In one case removal of bone had revealed a large blood-clot between the dura and pia, which had given rise to pachymeningitis. In another case, in the service of Dr. Janeway, the speaker had been asked to operate. In this there had been partial paresis of one side with semi-unconsciousness. The paresis had been upon the same side as the injury. He had not operated at once, and meantime the patient had died. The compression had been found to be on the same side as the injury.

Dr. T. H. MANLEY showed a piece of bone removed from the skull of a child of four years of age who had fallen down four flights of stairs. Four days after the accident there had been paralysis of the left side. The speaker had found the portion of skull shown imbedded in a mass of clotted blood. In cleansing he had employed no chemical solutions. The child had got along quite well except that there now existed a cerebral hernia, which he must confess he would be glad to know how best to treat.

**Hysterectomy for Prolapsus Uteri.**—Dr. McCOSH also related the case of a woman, forty-two years of age, who for twelve years had suffered from prolapse of the uterus. For six months there had existed an irreducible mass composed of the enlarged uterus, the entire bladder, and the dragged-down rectum. This mass had been of the size of a Derby hat and external to the vulva. After the patient had rested a week in bed the mass had been still irreducible. A sound passed into the urethra had defined the limits of the bladder entirely outside of the vulva. The uterus, which had been retroverted and of double the normal size, had been dragged two inches below and behind the vulvar orifice. The speaker had decided to do hysterectomy, and dissection had been commenced within half an inch of the os uteri and carried upward until the lower portion of the broad ligament had been reached, and this had been tied with silk and cut. Dissection had then been continued in front and behind and carried upward until the peritoneal cavity had been opened. The remainder of the broad ligament had then been secured by two sutures on each side and the uterus had been removed. It had measured six inches in length. There had still remained a large cone of vaginal wall nearly an inch thick and the bladder and rectum. The vaginal mass had been carefully dissected away. The remaining prolapsed mass could not be returned at the time of operation and had resisted all efforts at reduction until the twentieth day. The bladder had gone back into place and three months had now elapsed since the operation without recurrence of any protrusion of the parts. The speaker, of course, recognized the fact

that too short a time had elapsed to allow of this case being used in citation as to the ultimate value of the operation.

**The Thiersch Method of Grafting in Plastic Operations on the Nose.**—Dr. C. A. POWERS presented a female patient upon whom he had operated for vascular papilloma springing from the nose. Three fresh grafts had been taken from the arm and the wound had healed throughout. On previous occasions the speaker had applied a single large graft in regions where the skin could not be approximated, and twice these grafts had failed to catch. He could only account for this by the assumption that the ligatures used had interfered with the blood-supply. He thought that where a single large graft would catch the cosmetic effect was better. When the graft was taken from the arm it was introducing a skin different in color from that at the site it was to occupy.

**Errors in the Use of the Cystoscope.**—Dr. L. B. BANGS, in a paper on this subject, said that there could be no doubt as to the value of the cystoscope as an instrument of precision and an aid to diagnosis. Conditions of the bladder formerly unrecognizable were now clearly definable by the use of this instrument. Stone in the bladder, cysts, ulcerations, localized hyperæmias, infiltrations of various types, and tumors might all be seen and diagnosed definitely. The situation of the mouths of the ureters could be detected and inspected with perfect accuracy; and by means of the tube attachment by Dr. Brenner, of Germany, these channels might be catheterized and the fluid descending from each kidney reserved for microscopic examination. But the cystoscope had its limitations and fallacies, and the first step in the direction of their removal was to recognize them. One of the symptoms frequently met with in diseases of the genito-urinary organs was hæmaturia or blood in the urine. Sometimes the source of this was extremely doubtful. A diagnosis was often made with resort to instrumental observation, and, notwithstanding the existence of the cystoscope, we might still have to resort to the older and more ordinary methods of diagnosis. In other words, the amount of blood present in the urine or in the bladder might be so abundant that the cystoscope would be of no use and reliance would have to be, as formerly, upon the process of exclusion. Another difficulty arising from present imperfection in the cystoscope was the possibility of optical illusions which were at times very deceptive—such, for instance, as the magnifying of the object by too close an approximation to it of the window of the instrument. It should be borne in mind that an object seen through a fluid medium was more likely to be magnified when looked at directly or outside of the body. Only the skill which came from frequent practice could enable the operator to eliminate this source of error. Again, it had frequently happened to even the most skillful to see things which did not really exist or which gave to the eye the appearance of existence. The bladder had been opened for the purpose of removing tumors seen through the cystoscope which when the bladder was opened were not present. Another limitation to the use of the cystoscope was in the case of elderly men in whom stone was suspected and in whom there was a tortuous or long prostatic urethra making catheterization difficult or impossible.

The speaker did not wish to have it inferred that he was not an enthusiastic user of and believer in the cystoscope. He employed it under all possible circumstances. His practice had been enlightened by it and cases had been cleared up and successful treatment made possible by the knowledge which it gave. He did urge, however, that difficulties existed only to be overcome by long experience with the instrument and by the most careful exclusion of all sources of error.

Dr. W. K. ORIS thought that there existed an idea that it was only necessary to possess a cystoscope to make sure of the diag-

nosis. As to the question of hæmorrhage into the bladder, it was wonderful how small an amount of blood would make it impossible to see anything with the cystoscope. He thought that it would be rare that hæmorrhage from the kidney would be sufficiently rapid to mar the use of the cystoscope. Bleeding from the kidney was comparatively readily recognized, but when the hæmorrhage was from the bladder the resorption test by iodide of potassium would give the knowledge that the bladder was at fault, and then the cystoscope could be used to define the exact cause. Another source of error in the French instruments was the spherical aberration, so that a perfectly flat surface examined in the phantom bladder looked like a globe. The speaker and Dr. Stratford were now at work upon a cystoscope which they hoped would give a flat field.

Dr. WILLY MEYER said that Nitze and other authorities had always maintained that it was necessary to have five ounces of water in the bladder when making an examination, and he thought that when this point was observed the eye could be more readily trained. In stretching the bladder by fluid a syringe—not a fountain syringe—should be used. When there was hæmaturia it was impossible to view the bladder, and it was better to wait. It was also necessary that the urethra should admit of the passage of a catheter of 23 caliber.

The CHAIRMAN inquired if there was any record of accident occurring as a direct result of the use of the cystoscope.

Dr. BANGS had not heard of anything other than some slight burning from too prolonged contact of the lamp.

**The Treatment of Hæmorrhage.**—Dr. R. H. M. DAWBARN, in a paper on this subject, advocated the more frequent use of the Spanish windlass where this measure was indicated. He also gave the particulars of a case which he had successfully treated in the following manner: Being able to make out the pulsation of the femoral artery, he had introduced a hypodermic needle, and, having verified its position by seeing the blood enter the barrel of the syringe, he had removed the barrel, and, attaching a soft-rubber catheter to the base of the needle, had used this as a connection to a Davidson syringe apparatus. A warm saline solution had been employed and passed thus into the arterial circulation. The case had been one of imminent gravity, and the result of the treatment most efficacious.

Dr. W. W. VAN ARSDALE had found these saline solutions of little benefit. Certainly his experience had been limited to operative cases. The most satisfactory results, lives having been saved, he had got where blood had been used with the saline solution. The injections had all been intravenous.

The CHAIRMAN thought more experience should be gained before accepting the method of puncturing the femoral with even so small a needle as a matter of routine. He could indorse the value of the saline solution, and made it a point to have in readiness a quantity of proper strength for addition to a given quantity of water. He thought a vein could usually be entered without much difficulty, and that for the present he should prefer that method of making these injections.

#### SECTION IN PEDIATRICS.

*Meeting of November 12, 1891.*

Dr. A. CAILLÉ in the Chair.

**Soxhlet's Modified Milk Sterilizer.**—Dr. LOUIS FISCHER demonstrated the working of a recent modification by Professor Soxhlet of his now widely known apparatus for the sterilization of milk for infant feeding. The recent device, which had been patented in Germany, consisted in placing a small rubber disc upon the bottle containing the milk. This disc was held in place by a loosely fitting metal cap. When the bottle was heated the contained air, in expanding, escaped by lifting the little

disc. When cooling was commenced there was a vacuum above the milk in the bottle and the air-pressure without drove the disc home upon and partly into the neck of the bottle and effectually sealed it until the disc was forcibly removed. The disc could not be replaced after being removed.

**The Physiological Importance of the Proximate Principles.**—Dr. W. H. PORTER read a paper on this subject.

The CHAIRMAN said that the equivalent of foodstuffs had been ascertained, as shown in the dietary of animals, but that in pathological conditions we did not always know what the changes were.

Dr. W. H. THOMSON said that the paper was of value as it dealt with the physiological chemistry of the urine and the physiological importance of water. In high-tension pulse and in other symptoms of lithæmia water was required, and from it we obtained a therapeutic result. Probably the system got water in some other way than by the mouth. He had observed patients with diabetes insipidus who passed two or three times as much as they had taken. Workmen in glass factories would lose two or three pounds in sweat and in a little time regain their weight without drinking. We had probably the power of acquiring water from the air as well as of losing it in perspiration. He regarded the mineral waters as of value in cases where the portal circulation was at fault, but thought that the contained chloride of sodium did the most of the good. He hesitated to admit physiological chemistry to the bedside, and he doubted whether we could follow these foods in the abstract and say that too much or too little of this or that was used. He would not give meat, as indicated in the paper, to children, but would rather employ vegetable albumins and milk and thus avoid nervous disorders.

Dr. A. ZEH thought that in cases in which too much starch had been taken albumin and skimmed milk should be given and the starches and sugars be limited.

Dr. PORTER did not regard the internal mechanism and the laboratory as identical. He considered milk the fundamental article of food. In infancy, however, the biliary and pancreatic ferments being limited, there was not a complete digestion of fat and proteid. The milk sugar caused a little fermentation, which was productive of peristaltic movement. He had found that by the use of proteids he could drive uric and oxalic acid from the urine, when by the continued use of a diet of starches and sugars he had failed. Uric-acid infarcts in the fœtus and infant he believed to be due to the use of improper food by the mother.

## New Inventions, etc.

### A NEW NEEDLE-HOLDER.

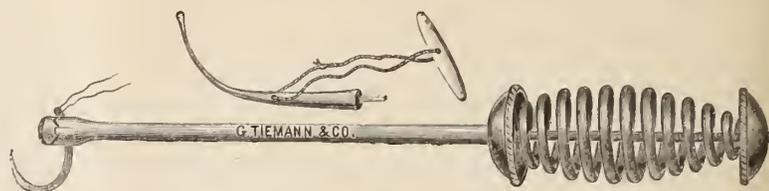

By G. WILLIS, M. D., L. R. C. P. (Ed.),  
GREENVILLE, CAL.

I VENTURE to present to the surgical profession a new pattern of needle-holder, devised to carry the ordinary surgical needle, Hagedorn's needle, and Thiersch's spindles for ligature *en masse*. The holder consists of four very strong and simple parts:

1. A hollow tube with a distal plate.
2. A central stem.
3. A spiral spring.
4. A proximal (or heel) plate.

The spring forms the grip or handle; the proximal plate screws on to the central stem, has a milled edge, and compresses the spiral spring, which, in turn, compresses the stem and tube. By turning the proxi-

mal plate the needle grip is rendered invincible. When this heel plate is unscrewed the four portions of the instrument drop apart. Release of the needles is effected by compression of the spring, one hand only being required.

The advantages alleged for the instrument are simplicity of construction, aseptic form, the ease with which it may be instantly separated for purposes of boiling or cleansing, and the combination of Thiersch's most useful spindle apparatus with a simplified Hagedorn and other needle-holder.

Needles pass in at a right angle or obliquely upward. The instrument in its present form has been developed from my rough model by Messrs. George Tiemann & Co., of New York, from whom it may be procured. My best thanks are due these gentlemen for the skillful manner in which they have expanded my crude idea.

## Miscellany.

**The Brain of a Great Chess Player.**—An article On Blindfold Play and a Post-mortem, by Charles Tomlinson, F. R. S., published in the *British Chess Magazine* for August, 1891, serves as a text for the following editorial in the *British Medical Journal* for December 19th:

To most people playing at chess seems rather too strenuous an effort to be called an amusement. It is said that ten years of incessant study and practice are necessary to make a first-rate chess player. A good deal of his excellence consists in the memory of problems, and we are told that, since the institution of a time limit, the professionals in match games endeavor to construct intricate positions for which correct solutions can scarcely be found within the time at command. Nevertheless, some strong-headed people go a good deal beyond this; they can play a game blindfold—that is, the moves are made without seeing the board. Blindfold play, Mr. Tomlinson tells us, is at least a thousand years old, but it has taken a marvelous development in our own day. "When it was revived by Philidor," writes Mr. Tomlinson, "the world was astonished at his skill in playing two games at once without seeing boards or men; and it was thought that his brain during the performance must have been in a fearful state of tension. To the surprise, however, of all present he was quite at his ease, and even mingled light conversation with his play. In our own time Morphy played eight games without sight of boards or men; Blackburne played twelve in my presence, Zukertort fourteen."

Mr. Tomlinson tells us that Blackburne, during his blindfold performance, "sat on a low platform with his face to the wall, his eyes closed, and he grasped tightly the fingers of one hand in the grip of the other; he took no refreshment within the ten hours that the contest lasted except some lemonade." When asked how he slept after such a task he replied: "Badly, unless I take time to cool down, but if I go to bed about three hours after the play I don't experience much inconvenience." This is the usual result of intense mental exertion.

Of course the blindfold player must have a distinct mental image of the chess board with its sixty-four black and white squares, and also the position of the different pieces of chess varying with each move; but in the case of a man playing a dozen games at once this requires an enormous effort of memory. The success of the game must greatly depend upon the distinctness of the image. "Zukertort's account of the mental process was that he had somewhere in his brain fourteen boards, numbered from 1 to 14, placed in separate closets side by side in a row, each closed by a door; having made his move, say, on No. 1

board, the door closed and that of No. 2 opened, and in this way he passed in due order from one to another until he arrived at No. 14. He dismissed from his mind, at the moment, all the boards except the one before him; a mental glance enabled him to realize the position, receive his adversary's move, and dictate his own. Then, passing on to the next, he acted in like manner, just as if the apparatus described were actually before him." This is in accordance with precedent; not only would it be necessary that the boards should be mentally realized, but each would need some distinctive mark to prevent confusion. We are told that the process is so exhausting that Morphy became deranged and died under melancholy circumstances while still young. Zukertort and La Bourdonnais are also said to have died from illness produced by the intense mental strain of these blindfold games.

The most wonderful piece of information is still to come. A great blind chess player, Mr. Richard Rookwoode, could play twelve blindfold games with ease, but could not get on with fourteen. This gentleman died about a year ago, and his brother, "who is a skillful anatomist and physiologist," obtained permission to examine the brain of the great blindfold player. He took for his basis phrenology, which is assumed to be the explanation of the functions of the brain at present in acceptance. The organ necessary for a good chess player is locality, other faculties being subsidiary. On examining the portion of the brain occupied by the organ of locality it was found that "the molecules had arranged themselves into forms somewhat resembling chess-boards, with certain marks on the squares supposed to represent the final position of the pieces in the last twelve games that had been played blindfold. Twelve positions were thus probably indicated by the aid of the highest power the microscope could supply; the thirteenth or fourteenth boards, or what might represent them, were blurred and indistinct." It is lucky that Dr. Rookwoode, in making his microscopic sections, went the right way—for example, if he had cut at a right angle instead of horizontally to the surface of the molecular chess squares, his important discovery could scarcely have been made. For further details we must still wait for "the elaborate Memoir which is to be submitted to the Royal Society as soon as the numerous illustrative drawings are completed. The purely anatomical details are to be laid before the College of Surgeons." This makes some questions on mental philosophy delightfully easy. We wonder whether in molding a statue or painting a picture the "molecules" of the brain of the sculptor and painter arrange themselves into a little model or sketch. This should be sought for when the next great sculptor or painter dies, and the result might be laid before the Royal Academy of Laputa.

**The Question of paying Hospital Nursing Pupils** has lately been discussed by various correspondents of the *Evening Post*, one of whom, Dr. J. West Roosevelt, writes as follows:

The letters of "J." and "F. T. D." present a question of importance to the public. The education of nurses is a matter of moment. Having taken rather an active part in a discussion of the same topic in certain professional journals, I have read the communications of your correspondents with great interest. May I be allowed to say something in the *Evening Post*?

It is necessary to state clearly the question, for the public in general have not yet become familiar with it. It may be summarized as follows:

Training-schools for nurses give their pupils an education which enables them to earn a living, provide them with board, washing, and lodging during the period of instruction, and also pay them more or less money while teaching them their profession. Is it right to pay them?

The policy adopted by the Government at West Point or Annapolis has no relation to the subject. As "J." points out, the cases are not parallel; but if they were, it would make no difference. The methods of the Government are not necessarily right. In the particular instances alluded to the Government is undoubtedly right, but as the training-schools do not educate nurses for the purpose of providing trained employees to do needed work for the benefit of these schools, while the Government has this purpose, and this alone, in view, there is no resemblance between the aim of the Government and that of training-schools.

It is possible, though not at all probable, that nurse pupils really should be paid. If a sufficient number of equally good pupils can be had in no other way, they must be offered money. In that case also there can be no justice in calling the wages "charity," for they are fairly earned. The demand for pupils exceeds the supply. Nurse-pupils while under instruction necessarily work, and few can understand how hard they work, for the good of the sick in hospitals; one reason for the existence of training-schools is to provide good nursing for hospital patients. Indeed, I believe that this was the first object in the minds of those who established the oldest institution of the kind in this country. Hospital nursing is very hard work, and must be paid for in some way. If the education given is a sufficient reward, any money paid is not earned, and therefore those who give it offer, and those who take it accept, "charity" in the same sense meant by "J.," or, to speak plainly, alms. Moreover, it is hard to see what excuse the managers of trust funds, such as those belonging to these schools, can offer for the needless expenditure. Trustees have no right to be sentimental. They are bound to make the best use of their trust. It is their duty to get the best pupils, and it is also their duty to spend as little money as possible. The fact that at one school during the year 1890 there were forty five applicants for each vacancy surely makes it more than probable that the pay is not necessary.

There seems to be an idea in the minds of many that the schools are intended to provide certain unfortunate young women (especially those in "reduced circumstances") with a means of livelihood. This is utterly false. They exist to teach competent women to become nurses, and to furnish hospitals with good nursing. The previous circumstances of an applicant (except in so far as they affect the question of her fitness), her misfortunes, her social position, the "pull" she may have, her extreme goodness of heart, the fact that her father was a missionary or something equally meritorious, are unimportant; her ability to become a nurse is the only question to be considered. The managers of these schools can not, in justice to their trusts, knowingly admit incompetent scholars. As to paying the latter, their action must be determined by the law of supply and demand.

As a most sincere friend of the training-schools, and one who quite as much as "F. T. D." resents any attacks upon the dignity of the nurse's calling, I feel that the pay system is a source of danger to the very existence of the former, while as to the effect of giving unearned money upon the dignity of the recipient—is it likely to be elevating?

**The Diagnostic Significance of Alterations of the Reflexes.**—Dr. James Jamieson, of Melbourne, contributes the following article to the November number of the *Australian Medical Journal*:

In spite of the great increase of knowledge in the department of diseases of the nervous system many questions of almost fundamental importance still remain unsettled. It might rather be said, indeed, that because of the recent progress in their study, the whole subject is constantly being subjected to revision. This holds good of the significance to be attached to alterations in the reflexes, even though the chief points in the interpretation of these alterations are generally accepted as settled. Of all the phenomena of this kind, which can be elicited in the various regions of the body, those to which appeal is most frequently made are the reflexes at the knee and ankle joints. The alterations in the knee and ankle reflexes are chiefly of service in the diagnosis of diseases of the spinal cord and its nerves, though not of these exclusively; and, for general diagnostic purposes, they are undoubtedly the most important of the reflex phenomena producible in the trunk and limbs. The others may be helpful in confirming the indications which they provide, and may further be required for definitely fixing the exact seat or extent of a lesion. But for determining the existence of spinal disease, or fixing its characters, the evidence supplied by observing the changes in the knee and ankle reflexes is of supreme importance. If I limit myself, therefore, to a consideration of that evidence alone, there are good practical reasons; and perhaps I shall be pardoned for beginning this discussion with a reference to the mechanism of production of the patellar and other similar reflexes.

The parts of the nervous apparatus, in the so-called reflex arc, are these: (1) An afferent nerve or nerves conveying an impression from the surface to the nerve center; (2) a sensory apparatus, cells in the

posterior column of the cord, by which that impression is received: (3) a motor apparatus, cells in the anterior column, to which the impression is transmitted, and by which, in turn, an impulse is communicated to (4) an efferent nerve or nerves, conveying that impulse to certain muscular fibers, which respond by contraction. It is perhaps necessary to postulate (5) a system of fibers by which communication is made between the sensory and motor parts of the central apparatus. Practically, however, we know nothing about any independent affection of this portion of the arc; and it may be doubted if any interruption in the transmission, from periphery to center and back to muscles, could be explained by a break in the communications there.

For the production of a normal reflex, like the knee-jerk, we have to assume the integrity of all these parts of the sensori-motor apparatus forming the arc.

An alteration of the patellar reflex may be in the way either of increase, or of diminution even to complete abolition. And while abolition of the reflex is something definite, it is not by any means easy to define what the normal condition is, or to say with certainty whether an apparent increase or diminution is actually a pathological condition. Certainly, there are great differences in different persons, as regards the ease with which the jerk is produced; and even considerable differences in the same person at different times, and independently altogether of the supervention of disease of nerve or nerve center. In occasional, though probably rare, cases the knee-jerk can not be elicited, and that though there is no other evidence of disease of the nervous system. It can not, therefore, with certainty be said that even absence of patellar reflex is a pathological condition, though its abolition, in a person formerly exhibiting it, would be more significant. Alterations of the knee-jerk, therefore, in the way of diminution especially, are not always easy to estimate for diagnostic purposes.

In the case of the ankle joint there is nothing which can be regarded as strictly analogous physiologically to the knee-jerk. The muscles of the calf may offer some involuntary resistance to dorsal flexion of the foot, and the same muscles may contract involuntarily, when the tense Achilles tendon is struck. But diagnostic significance does not belong to the degree of readiness with which such contraction takes place. The phenomenon connected with this joint, which alone has importance, is ankle clonus, and its significance is so far definite that its production is always proof of the existence of some abnormal condition. What the conditions are, which lead to its production, will be considered later on, along with exaggeration of the patellar reflex, with which it is regularly associated. It may be said merely that these conditions are far more complicated and difficult of interpretation than those which cause diminution or abolition of the knee-jerk.

Taking abolition as something definite and ascertainable, it may be said that if its causes are numerous, they are also easily definable in the great majority of cases. We may leave out of consideration cases of severe shock to the central nervous system, as from injuries or cerebral hemorrhage, in which almost all the superficial and deep reflexes may be absent. But taking cases in which the patient is conscious, we may arrange the causes of abolition of patellar reflex according to the part of the reflex arc whose functional capacity is lowered or abrogated. Interruption of communication, along either afferent or efferent nerve, will of course lead to such abolition. But as sensory and motor fibres are so closely intermingled toward the periphery, it can not readily happen that interruption will be confined to the sensory or motor path respectively. Injuries of nerves may of course cause abolition of reflex contractions, but far more frequently the cause is neuritis. Of late years, multiple peripheral neuritis has occupied a large place in nerve pathology; and it must be reckoned among the most frequent causes of abolition of patellar reflex. The discovery of this symptom is important, therefore, in the diagnosis of peripheral neuritis, as it is seen in cases of alcoholic and diphtheritic paralysis for instance; though, for absolute differential diagnosis, account must be taken of other conditions present or absent, the history of the case often supplying important help.

Of pathological conditions seated in the posterior column of the cord, and interfering with the reception of sensory impressions, the best known is the degenerative change associated with the disease known as locomotor ataxy. Of the systemic diseases of the cord affect-

ing its motor portion, and by loss of function in that preventing the transmission of motor impulses to the muscles, the best known is anterior poliomyelitis. This, which is the cause of infantile paralysis, is occasionally found also in adults, and absence of patellar and other reflexes is one of its symptoms, being in fact one of the results of the very complete loss of motor power in this form of disease. But while we can thus distinguish cases in which the abolition of the knee-jerk is due to a lesion confined either to the sensory or the motor region of the cord, there are other cases in which both parts are involved. In diffuse or transverse myelitis, affecting the lumbar portion of the cord, loss of knee-jerk and of other reflexes in the lower extremities forms part of the large group of symptoms by which the disease is characterized. These causes cover the vast majority of cases in which there is loss of patellar reflex. It is noted as one of the symptoms which may be present in acute ascending (Landry's) paralysis; but there is no uniformity in this respect, and it is very probable that, under this heading, there have hitherto been often placed cases really belonging to other conditions, and notably to poliomyelitis anterior with paraplegic character, and multiple neuritis of a very severe and acute form. It is possible, also, that abolition of knee-jerk may be due to pressure on nerve roots, or on the cord itself, by tumors, or hæmorrhagic or other exudations within or outside of the spinal canal, or as a result of mechanical injuries (fracture, etc.). But if this symptom is to be manifested, the pressure must bear on the lumbar portion of the cord or its nerves, and specifically on the parts normally governing the reflex. If the pressure is higher up, and the lumbar portion is not affected, then the knee-jerk is more likely to be exaggerated. The history of the case will often go far to determine its nature, while the exact seat of the lesion may be fixed, partly by observation of the state of the reflexes of the trunk or upper extremities.

The general conclusion, therefore, is that diminution and ultimate abolition of the patellar reflex must be interpreted as due to a lesion, acute or chronic, mechanical or pathological, affecting one or more of the parts already enumerated as making up the reflex arc. The lesion, if not actually destructive, must at least be such as to interfere with the transmission of impressions from the surface to the sensori-motor center in the cord, and back again to the muscles. The lesion need not be, and generally indeed is not limited to that portion of the cord or its nerves; but whatever other portions of the nervous system may be affected, that segment certainly is; and in so far the symptom is helpful in determining not only the nature of the lesion, but to some extent also its seat.

If the causes which lead to lessening or abolition of the patellar tendon reflex are thus on the whole plain, it is not so with those which lead to its exaggeration. The knee-jerk may have an increased range, or be too easily produced, in many states other than organic diseases of the nervous system. In tetanus and in poisoning with strychnine it is increased in marked degree; and so it may be in hysteria. The same may readily be the case also in febrile states, or in emotional conditions of various kinds. In these latter it is most probable that the exaggeration is, in its nature, practically the same as the intensification which is obtained by Jendrassik's procedure—viz., causing the person under observation to make some voluntary effort, such as pulling at the hands which have been hooked into each other. It should always be remembered, however, that increase or exaggeration of a reflex is only relative, and its reality should not be too hastily assumed. If the person's normal or ordinary condition is known, the determination of an increase may be easy and safe; but otherwise it should be accepted as real only when present in marked degree. We have a useful test of its reality, or at least as to the presence of any organic nervous disease as its basis, in its association with or independence of the occurrence of ankle clonus. It is safe to assume that the latter always has some abnormal state of the nervous system as its cause. For, just as it may be found where the muscles of the calf have been quickly exhausted by standing on tiptoe, so it may sometimes be found after an epileptic attack, and possibly in other states of exhaustion. But these causes of the production of ankle clonus are generally obvious enough, and the phenomenon itself, when so produced, is usually not marked, and the artificial susceptibility is of short duration.

There are cases, however, in which there is room for uncertainty

whether a case of paresis or paralysis is a hysterical manifestation, or is actually due to organic disease. It is a common observation that, in hysterical paralysis, there is habitually exaggeration of reflexes, in addition to other peculiarities. Still, as the same is true also in many cases of paralysis from disease of the brain or cord, this condition has but a relative diagnostic value. But the check, supplied by testing the ankle condition, then becomes of extreme value in doubtful cases. If the increase of the patellar and other reflexes, superficial or deep, has ankle clonus as its accompaniment, the presumption in favor of the presence of organic disease is immensely greater; while absence of clonus, under these circumstances, if not absolute proof, is very strong evidence that we have to deal with nothing more formidable than hysterical paresis.

There are three conditions in which exaggeration of tendon reflexes in the lower extremity or extremities is regularly met with: (1) In hemiplegia of cerebral origin, at some stage of its course; (2) in sclerosis of the lateral columns of the cord, whether it be the pure form, known as *spastic paralysis*; in the mixed form, known as *amyotrophic lateral sclerosis*, in which the anterior gray column is also involved; or in *disseminated sclerosis*, in which the exact grouping of symptoms must depend on the distribution of the degenerated patches; and (3) in conditions interfering with or stopping conduction from the lower part of the cord to the brain, and *vice versa*. These are chiefly transverse myelitis and pressure on the cord by tumors, or as the result of disease or injury of the vertebrae. To produce this effect, it is manifest, however, that the disease or injury must be seated clear above the reflex arc, which must itself be intact. It is in these cases that careful investigation into the state of the other reflexes of the trunk and upper extremities is needed, for determining the exact level of the lesion in the cord, whether it be in the dorsal or the cervical portion.

Conditions, in many respects so diverse, having in common this symptom of exaggeration of the reflexes, the question at once arises whether the mechanism of production is the same in all. The purely reflex or automatic centers in the cord being subject to regulation or inhibition by the higher centers in the brain, it is a most natural and generally accepted opinion that exaggeration of reflexes may be, and indeed often is, the result of mere withdrawal of the subordinate spinal centers from the control of higher centers seated in the cerebrum. This explanation covers sufficiently the majority of cases in which exaggerated patellar reflex is found, whether the morbid condition be hysteria, an epileptic attack, pressure on the middle or upper part of the cord, or a cerebral lesion producing hemiplegia. But, though this be admitted, there remains the question whether such withdrawal from cerebral control supplies a sufficient explanation of all cases, and in particular of primary lateral sclerosis in which the increase of reflex activity is most marked. It is held by some authorities that the exaggeration of reflexes in lateral sclerosis, whether primary or secondary, is, like the contractures which are another prominent symptom, the result of irritation in the cord itself, caused by the formation and subsequent shrinking of the new tissue deposited in the lateral columns chiefly. That irritation of the cord may cause increased reflex activity need not be questioned, tetanus and strychnine poisoning being instances of it. But it is a fair objection to this explanation that the sclerosis is essentially a degenerative process of slow production, and therefore not of the kind which would be expected to produce an increase of activity in the part affected, or in those adjacent to and standing in close functional relation with it. Is it not far more likely, indeed, that in this, as in the other cases already enumerated, the exaggeration of the patellar reflex and production of ankle clonus are due to the cutting of communication between the cerebral centers and the lower spinal ganglia by degeneration of the great path in the lateral columns? Even where, in a case of hemiplegia, the exaggeration of reflexes appears to become more marked in the paralyzed extremities, when secondary descending degeneration has set in, it is not necessary to assume irritation of the cord as the cause. It is just as rational to explain it as the consequence of more complete withdrawal of the spinal centers from cerebral control, when to the lesion of the brain there comes to be added degeneration of one of its main paths of communication with the spinal centers. Light is thrown on the mode of production

of exaggeration of knee and ankle reflexes by the phenomena observed in cases of hemiplegia, accompanied by early rigidity. One such case, under my care lately in hospital, was of interest in this respect. The case was one of right hemiplegia, with partial aphasia and slight facial paralysis. There was great exaggeration of reflexes on the paralyzed side, ankle clonus being very easily produced; and there was also some exaggeration of knee-jerk on the left side, with distinct, though less marked, clonus. After a time there was great improvement, the rigidity of muscles relaxing, the clonus disappearing altogether on the left side and becoming less distinct on the right, *pari passu* with the recovery of power over the limbs. Here, evidently, descending degeneration and associated spinal irritation were not the cause of the knee and ankle phenomena, as they and the rigidity accompanying them could not have been expected to pass off as they did during a stay of a few weeks in hospital if they had been consequent on a secondary degeneration of the motor tracts in the cord.

The balance of evidence, therefore, is in favor of the doctrine that increase of knee-jerk and ankle clonus have a similar mode of origin, whether the lesion with which they are associated be seated in the brain or in the cord. That mode of origin we must take to be an unregulated action of motor spinal centers, owing to withdrawal of control by the higher center in the cerebrum. It is only by careful observation of associated symptoms that we can determine what the nature of that lesion is and what is its exact seat.

Leaving out of consideration temporary conditions operating in various ways—such as shock, febrile or emotional states, toxic influences, etc.—and taking account of actual pathological conditions of the nervous system only, it may be said that the general laws which govern alterations of the knee and ankle reflexes are these: I. Diminution or abolition of the reflexes is caused by conditions which interrupt the communication of impressions and impulses in the reflex loop whose spinal segment is seated in the upper lumbar portion of the cord. II. Increase of patellar reflex and ankle clonus are due to withdrawal from cerebral control of the same portion of cord, which must itself be intact, that loss of control being due either to a lesion in the brain itself or in the cord at some higher level.

But when the laws have been thus formulated it remains to be considered whether there are exceptional cases or conditions in which they do not hold good.

In 1882 Dr. Charlton Bastian expressed the opinion that certain cases of lax paraplegia, in which there is loss of sensation as well as of motion, and absence of patellar reflex as well as of ankle clonus, owe the latter peculiarity to the fact that the spinal lesion is complete transversely, whether it be softening or separation mechanically from some injury. He held, thus, that there are cases of spinal lesion in the dorsal or cervical portion, cutting off the lumbar portion completely from connection with the brain, in which, notwithstanding, the reflexes are abolished instead of being increased. This view did not commend itself to authorities on the subject of nervous diseases. Even with the proofs and arguments contained in Dr. Bastian's book, *Paralyses: Cerebellar, Bulbar, and Spinal*, the doctrine that transverse lesions are and must be attended with exaggeration of reflexes, if the lumbar portion of the cord is intact, continued to be held. In a communication published in the *Medico-chirurgical Transactions* for 1890, however, he returns to the subject, and, by the help of cases carefully observed during life and examined after death, he establishes the correctness of his opinion, which has since received confirmation from other observers. The duration of some of the cases makes it impossible to explain the absence of reflexes by the existence of shock, as was at first suggested by some critics. The cases showed not only that complete transverse destructive lesions do cause abolition of reflexes, but, further, that the descending degeneration of the lateral columns which follows the lesion does not cause rigidity and contracture in the paralyzed extremities. It seems to be almost a necessary inference that the spastic condition observed in lateral sclerosis, primary or secondary, is not due to the sclerosis as such, as is taught by most authorities. The explanation of the great difference in the state of the reflexes in cases of paraplegia due to lesions of the cord in its middle and upper portions, beyond the circumstance that in some the lesion is a complete transverse one and in others incomplete, must at present be almost purely

hypothetical. Dr. Bastian, following an earlier suggestion by Dr. Hughlings Jackson, believes that we must assume a double controlling action by the brain over the functions of the cord. The cerebrum exerts a regulating or inhibiting influence over the purely spinal reflexes, and when this controlling influence is withdrawn, in consequence of cerebral lesions on the one hand, or sclerosis or other lesions affecting the lateral columns on the other, the spinal centers act in an exaggerated and unregulated way. The controlling or inhibitory influences evidently pass downward along the pyramidal tracts. But how account for the absence of this exaggeration when the lesion affects a complete cross-section of the cord, since certainly the controlling influence must here be completely withdrawn? The suggested explanation is that the cerebellum has, as part of its function, the duty of keeping up the state of *tonus* in the muscles, acting through the cord; and that its influence in this way is communicated downward in some part of the sensory columns. When this stimulating or tonic influence is withdrawn, by destruction of the sensory tracts in the posterior and central portions of the cord, the spinal centers are unable to effect a response in the form of a reflex contraction.

The importance of this new doctrine is considerable in regard to diagnosis, and still more to prognosis, and sometimes to treatment. In cases of injury to the spine, followed by lax paraplegia with complete loss of knee and ankle reflexes, the necessary conclusion would seem to be that, if this condition persisted after shock had passed off, recovery would be hopeless, and that no benefit was to be expected from any operative measures adopted with the view of relieving pressure. So long, on the other hand, as the reflexes are preserved, even though the paralysis is very complete, there is hope of recovery, since the whole thickness of the cord has not been affected by the destructive lesion. And that recovery may occur, even under very unfavorable conditions, is clearly shown by a case of Charcot's, in which the patient had been affected with and recovered from paraplegia, associated with vertebral disease and angular curvature. When she died, two years after, it was found that the spinal cord, at the level where compression had existed, was no larger than a goose-quill, and when cut, its section was not more than about one third of that of a healthy spinal cord examined in the same region. (Charcot, *Diseases of the Nervous System*, second series, p. 80, N. S. S. translation.)

Locomotor ataxy has already been referred to as one of the diseases very regularly associated with loss of patellar reflex. That the association is not an absolutely constant one has been repeatedly shown, some at least of these exceptional cases being where the disease began in the cervical portion of the cord, instead of in the lower portion, as is the rule. Occasional cases of hemiplegia, occurring in persons already the subjects of locomotor ataxy, have been recorded, and in a few of these it has been noted that the patellar reflex was present. But with the exception of a case, reported by Dr. Hughlings Jackson and Dr. Taylor (*British Medical Journal*, July 11, 1891), it does not seem to have been noticed whether the knee-jerk was absent previous to the coming on of the hemiplegia. In this patient the ataxic symptoms had existed for about twelve years when he came under observation. He had then had two attacks of hemiplegia, the second eight days before admission, the right side being affected, and the knee-jerk absent on both sides. Forty-seven days after the second attack it was noted that there was slight return of the right knee-jerk. Two years after, the right knee-jerk was readily obtained, and a slight jerk could also be got on the left side, though with difficulty. Some of the ataxic symptoms had improved, while others had remained stationary, or become aggravated. Here, then, there was a remarkable instance of restoration of a normal physiological phenomenon, apparently resulting from the addition of a fresh disease, a cerebral lesion with secondary lateral sclerosis of the cord, to the original disease, posterior sclerosis, which had caused its abolition. It is difficult to account for the restoration of reflexes in this case, and the authors of the paper only venture the suggestion that a few fibers had remained intact in the posterior columns, but that they had been insufficient to convey strong enough impressions from the periphery, till the sclerosis came on, and by stimulating the anterior horn made it more prone to respond to slight impressions. In view, however, of the cases collected by Bastian and others, in which the occurrence of de-

scending sclerosis, following lesion of the cord, led neither to increased reflexes nor contracture, it is not easy to accept the sclerosis in this case as, *per se*, the cause of the restoration of the patellar reflex. In accordance with the facts and arguments already adduced, it seems a more probable supposition that the descending sclerosis acted rather in the way of cutting off, more completely than before, any remains of cerebral control. In the absence of inhibiting influence, the few fibers left in the posterior columns might be in a position to convey impressions, strong enough to stimulate the now unrestrained automatic motor centers in the anterior horn. Whatever be the correct explanation, it remains an established fact, not only that the patellar reflex may continue in well-marked cases of locomotor ataxy, but that it may possibly be restored after having been abolished.

Perhaps the most important lesson to be derived from this study of the relation of leg reflexes to pathological conditions of the brain and cord is the need for caution in arriving at conclusions on too narrow a basis of observation. Pathognomonic symptoms are rare, and if it be necessary in all diseases to make symptoms, and even groups of symptoms, serve as checks on each other, for diagnostic and prognostic ends, above all must this be necessary where conditions are so complicated as they are in the nervous system and its diseases.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or profuse histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

Original Communications.

PSEUDO-EXPERTS IN LUNACY.\*

BY S. GROVER BURNETT, A. M., M. D.,

KANSAS CITY, MO.,  
 CLINICAL LECTURER ON DISEASES OF THE MIND AND NERVOUS SYSTEM,  
 KANSAS CITY MEDICAL COLLEGE;  
 MEMBER OF THE NEW YORK MEDICO-LEGAL SOCIETY;  
 FORMERLY ASSISTANT SUPERINTENDENT, LONG ISLAND HOME OF NEW YORK  
 FOR DISEASES OF THE MIND AND NERVOUS SYSTEM, ETC.

In bringing this subject before you at this meeting I am not prompted by any selfish motive of radicalism, but rather for the purpose of drawing the attention of both the medical and legal professions to a subject which should interest us alike. Not only should it be of common professional interest, but worthy of consideration by all thinking people generally. It shadows the point where the two professions meet, and has always been a delicate and difficult chasm to bridge over—that all who are so unfortunate as to come within the pale of the law through either disease or crime, or both, might be guided over it to a rest of justice. Any efforts spent upon the solution of a question that means so much to the human family certainly should not be considered in vain though the reward be not in view.

That we may at once get at our text there is no better illustration offered us than in the case of Myers, of this city, who was adjudged insane on the testimony of the general practitioner. Myers, with a companion, was going about the country, so they aver, in search of work. Not having comfortable quarters for the night, they went to the depot where they could keep warm. Secing a man asleep, the companion remarked that he had money, when Myers proposed “to stun and rob him.” They secured an iron pin used for coupling cars and returned to the scene of the coming tragedy. Myers again proposed the killing, and asked the companion (a boy) to make the attack, but he refused, saying he was not strong enough. Myers then struck the sleeping man several times, each time breaking the skull. The money obtained was equally divided. Rational effort was made to escape, and it was only after the boy had turned State’s evidence that arrest was made. They were convicted, Myers receiving sentence of death and his companion life imprisonment. On the second trial Myers received the benefit of a “hung” jury, and a third trial accomplished his release on the ground of insanity. He went to the poor-farm for a few days, and then was allowed to go to his home.†

I do not propose to discuss this in full, neither is it intended to cast a personal reflection upon any of the gentlemen connected with this case; but in this brief history there are medico-legal points that should not be overlooked. First, Myers was the senior co-operator; he reasoned well

\* Read as the opening address at the annual meeting of the Missouri Valley Medical Society, at Council Bluffs, Iowa, September 17 and 18, 1891.

† I am informed that in obtaining the release of Myers from the poor-farm the plea was, they feared he would lose his mind if compelled to remain there. The absurdity of this is difficult to explain without being personal.

in planning and executing the crime in every particular, excepting the proposition made by the boy that the man had money. Myers proposed the killing, and, realizing the enormity of his crime, tried to use the boy as his tool, but, failing and realizing the possibility of making a failure of the deed through the boy’s lack of strength, he had the power to put his premeditated project into effect. Rational effort was made to escape. Equal division of the booty was exacted. These facts, all of which were indications of the mental state at the time of the commission of the crime and constitute the only reasonable facts upon which a verdict should be rendered in such a case, are certainly not in keeping with the verdict in this instance. Keeping the nature of the verdict in view—that of acquittal on the plea of insanity—and admitting that it be a just verdict, what are we to think of it when we recall the manner in which the individual was disposed of—turned loose to continue the destruction of human life in accordance with the dictates of an insane mind? There are two possible explanations of this, as the disposition of the case is directly opposite to the meaning of the verdict rendered—namely, undue consideration and illogical comprehension of the facts upon which a diagnosis of insanity should be made, or a determination to defeat justice to gain personal satisfaction, regardless of the dangers engendered in the future, to react again upon society by a repetition of the former deed.

I should regret to learn that we lived in a State whose statutes were so imperfect in offering protection to its citizens, and, in the face of facts here presented, I can not refrain from saying that others should not be anxious to share the reflections of such a contradictory verdict as was promulgated by the abettors connected therewith.\*

For the benefit of those who have not had the privilege of becoming familiar with medico-legal technicalities, and to show how delicate a consideration the subject requires, I have thought it best to give in brief a review, as near as I am able, of the indications arrived at, pointing out the peculiar mental conditions to which an individual should be subjected that he may be classed as an insane criminal. Among the great thinkers of the medico-legal world there has been going on for the past quarter of a century a “silent revolution” with reference to the doctrine of the legal handling of a class of culprits commonly designated, owing to the absence of a better nomenclature, as criminal insane.

\* In an interview with my friend, Dr. Willis P. King, whose testimony had much to do with the verdict in this case, he says the very appearance of Myers would immediately call to mind the theory of Darwin, and there was little doubt that his ancestors had not been walking on their hind legs very long. According to Dr. King, the boy mentioned was an overgrown youth with a criminal history in his family, and, knowing the weakness of Myers, he urged him to commit the crime. Dr. King would have me believe that Myers, when questioned, would be able to say which was right or wrong, but had not the power to avoid doing the wrong and adhere to the right when urged by the companion. This is an important technicality, and is possibly well taken; it is in keeping with the verdict rendered, and casts great reflection upon the legal disposition of the accused.

As usual in the advancement of scientific procedures, Germany was an early participant here, and long ago adopted in her criminal code of laws the proposition that "there is no criminal act, when the actor at the time of the offense is in a state of unconsciousness, or morbid disturbance of the mind, through which the free determination of his will is excluded" (Code of Germany, Sec. 51, R. G. B.). As we look a little farther we find the interpretations of the code of France agreeing in every particular, practically speaking, and gives great support to the efforts of the medical minds so ardently exercised in perfecting that which is of such medico-legal interest and utility. This silent revolution (so named by A. Wood Brenton, Esq.) has now reached the minds of England and America.

Judge Somerville says: "It is the same old fight of science against the crystallized prejudices of error and ignorance" (*Medico-legal Journal*, December, 1890).

To attempt to discuss the law as to the testamentary capacity of the insane, and the law as to their capacity to enter into the contract of marriage, etc., would be a presumption on my part as well as a digression; hence I will confine myself to a mentioning of the various legal requirements as have been prominent in the decision of lunacy cases from time to time, among the first of which was the "wild-beast" theory of Mr. Justice Tracy, which is of little interest to us to-day.

In succession of this came the great theory of Lord Mansfield—namely, "the right and wrong theory"—which in turn was revolutionized by the decision in the MacNaghten case. Judge Somerville's decision, in the case of *Parsons vs. The State*, 1881, Ala., 577, also alluded to by Mr. Breton, was rendered in the Alabama Supreme Court, June, 1887 (*Medico-legal Journal*, September, 1890, and December, 1890), and was also a repudiation of the right and wrong test, as affirmed by the MacNaghten case, just mentioned, which was a decision of the English courts, and gives its indorsement to the modern view that "no insane person who, through disease of the brain, has lost the power to choose between the right and the wrong, and to avoid doing the act in question, is legally culpable or accountable."

The learned members of the medical profession have long recognized this feature, and the efforts of both professions to bring about a test that would be compatible to law and medicine alike have been arduous and many. The great Dr. Ray, of England, was an early benefactor to us in this line by his approval of the charge in Haskel's case in these words: "The true test lies in the word *power*. Has the defendant in any case the *power* to distinguish right from wrong, and the *power* to adhere to the right and avoid the wrong?"

Many times in my asylum practice have I been called to recognize this feature among the inmates. Frequently relatives of the insane have said to me, It is pure cussedness in him, for he knows it is not right, still he continues repetition after repetition of the offense. Unquestionably, those of the medical world of any special training in this direction will affirm any efforts that will lead to a unanimous adoption of this "modern view" or test.

In the report of the Alabama Hospital for the Insane,

by Dr. Peter Brice, for 1889, we find him voicing the profession on this subject. He says: "The thousand patients now under treatment in our hospital, and thousands of others who have filled its wards during the past twenty-eight years, furnish unmistakable evidence, even to ordinary observation, of the fact that persons of diseased brains, affecting the mind, may be capable of distinguishing the moral and legal quality of a criminal act, and yet not be able to abstain from its commission. They know the right from the wrong, and do not hesitate to avoid it, but they can not choose between the two, and often deplore their inability to control their actions. It would, it seems to me, be a backward step, in both humanity and science, to place these victims of disease in the same category with ordinary convicts in whose behalf no such plea can be interposed. The whole question is one of disease or no disease to an extent which practically destroys the patient's power of self-control." He adds: "The medical profession is almost unanimous in its repudiation of the right and wrong tests of this disease, and the interest of society, humanity, and science would, in my judgment, be promoted by the adoption of the same view by our courts of justice."

This in brief gives us the most acceptable and recent medico-legal view of a mental condition for which the possessor should not be held responsible with reference to acts that may be judged as criminal; but here the question arises, By whom and upon what qualifications shall such a mental condition be determined, and what protection are we going to offer to society? Shall the testimony of an embryo M. D. in the general practice of medicine be acceptable in such cases? According to present usages such is allowable. An individual having once been found to be and declared to be an insane criminal by a court of justice, shall he be turned loose upon a sister State again to repeat his acts of violence in order that the State in which he was convicted may escape the expense of the maintenance of such a character? Dr. Gooding says (*Medico-legal Journal*, December, 1889): "The finding not guilty by reason of insanity of a person who has committed a capital offense should carry with it the presumption of continued insanity and the forfeit of the personal liberty of the individual." Fortunately, in our more densely populated States this class of cases is quite well looked after in the way of offering protection to society; it would seem quite apparent that errors in such instances were apt to be the outgrowth of slipshod medico-legal procedures, if they can be called medico-legal procedures at all. The insanity plea has become so popular that it is not difficult to see how hands stained with chronic criminality would be ready to accept any new resources of defense. In such instances it has been with the utmost difficulty and prolonged study of the case that some of our most learned men in psychiatry, who have spent a lifetime in its study, have been able to arrive at a definite, logical, and scientific diagnosis. There are reasons why the plea of insanity should be adopted; such individuals, having come into the hands of the law, would prefer incarceration in an asylum for a time, with the hope of an early recovery (?) and release from custody, than to suffer capital punishment. In the case of *Myers vs. the State of Missouri*

this process was shortened by turning him loose at once upon the State of Pennsylvania. According to Dr. Church (*Medico-legal Journal*, September, 1890), our first step in arriving at a judicious decision in these cases is a difficult one, as "the question of insanity is made a question of fact to be decided by a jury." No matter how intelligent be these twelve men, they are in no wise capable of rendering a judicious verdict upon such difficult problems as to whether the deed was the result of an obscure disease of the mind unless they are educated men in medicine, which is never the case. Upon the testimony of the medical expert, and the ability of the jury to comprehend the same, depends the solution of the question, and here we reach a point that may hinge the verdict according to the ability and character of said witness. If in the power of the attorney for the defense, he will not admit of any testimony, regardless of its proficiency, unless it points out his client's exit to liberty; upon such technicalities depends the clashing of expert testimony in lunacy cases. Were the judge alone empowered to select medical experts, this clashing would be avoided.

Again we are left largely to speculation, as the point at issue is not the mental state of the criminal at the time of the prosecution, but when the act was committed, dating probably from a few months to a few years prior to the rendering of the verdict. Charge any man, especially if he is a little below the average in his physiological stamina, with murder in the first degree, with convincing evidence for his conviction, give him from one to three years in jail to think it over, and certainly his condition may warrant the plea of insanity at the time of the prosecution. Such mental strains are sufficient to alienate great minds. If with this plea and a little legal diplomacy they can substantiate the fact that the accused was "kicked by a mule" when a youth, that some one in the same village had hysteria or some of the various neuroses, his chance for a transfer to a palatial sanitarium at the State's expense may be looked upon with favor; and should he be fortunate enough to reside in a State where more attention is given to the getting rid of, instead of the prosecution of, or care of such cases, he may be liberated in a few days after the rendering of the verdict with the proviso to skip the State and stay skipped. It is rational to state that a verdict rendered at the time of the prosecution must be based largely upon suppositions, and often illogical conclusions, as the mental state upon which the judgment should be made is at the time of the criminal act—always prior to the date of the individual's coming under the observation of both jury and experts. Upon the testimony of the latter will be based the verdict of the former, and, as it means life or death, justice or injustice, we have here placed before us the only class of testimony that should be accepted before a court of laws, and that is expressed in the word *ability*.

I care not how competent a general practitioner is, he is no more competent to pose as an expert in psychiatry than he is to perform the most delicate and critical operation in surgery. Were I, after having seen a half-dozen or possibly a full dozen operations of a capital nature, to proceed to usurp the functions of a finished operator, you would rise

up in a body and declare me mad. Then imagine a man who has seen a whole dozen cases of insanity in his practice—in half of which number he guessed at the diagnosis and in the other half accepted somebody else's word for it—coming forward at so critical a moment and offering a scientific diagnosis and prognosis upon which shall depend the life or death of the accused, and perhaps the conviction of the innocent or acquittal of the guilty, which, according to the decision in the Myers case, means liberty to the offender and danger to the public wherever he may roam.

The diagnosis of insanity, if made scientifically, is often difficult to minds of long and patient training. In criminal cases the examination should be made with two possible features in view—namely, a motive for malingering and the actual predisposing influences, and the condition of the mind present, just prior to, and at the time of the commission of the crime. For instance, the case of Nellie Bly, who passed under the observation of two of the best clinicians in psychiatry that this country has, had a motive for the deception. It is true her commitment was based largely upon circumstantial evidence, but it was so convincing that these learned men were deceived. Evidence of less convincing nature would be sufficient to cause an inexperienced psychologist, in the majority of cases, to testify to the mental incapacity of the accused. The very fact that Nellie Bly appeared in the insane pavilion of Bellevue Hospital among pauper insane cases, with no apparent cause for her appearance and actions, and that she was watched by competent persons to catch her off her guard with negative results, seemed ample grounds for committing her to the asylum; of course it was afterward conceded that she was simply feigning insanity in order to gain access to the asylum that she might expose the maltreatment which some supposed to then exist. In the Court the criminal has a strong motive for feigning insanity, and an error in its detection is a grave error, though difficult of solution at times; the error also of finding a man not insane when he actually is insane is often equally as grave. To show that the practitioner's examination is apt to follow the routine of his daily cases is illustrated by the following: Dr. —, of Jamaica, Long Island, was ordered by the Court to testify in the case of Mr. A. C., who was then in the asylum under my care and suffering from an intellectual type of chronic mania. The doctor examined the pulse, tongue, temperature, condition of secretory and excretory organs, etc., and could go no further. He asked me to give him testamentary evidence, some of which was to the effect that Mr. C. had at times hallucinations of sight and hearing and delusions of persecution. This he testified to in Court, and when asked to explain to the jury the significance of his testimony, he failed and was dismissed. Here is expert testimony offered the acceptance of which meant life incarceration in an asylum, and it was obtained in an interview of about thirty minutes with the patient. Unfortunately for the witness, he used words too large for his vocabulary and his weakness was exposed. The readiness with which some physicians hasten to swear an accused to heaven, or *vice versa*, based upon a meager interview or two of a few minutes each, certainly merits criticism.

Some of the difficulties in making a diagnosis in criminals supposed to be insane is illustrated by the following case which came under the writer's observation in the Tombs Prison, New York city:

The charge was grand larceny in the first degree, which meant, if convicted, five to ten years in prison. My friend, Dr. Matthew D. Field, examiner in lunacy for the city of New York, was sent to see him during the fifth week of his confinement at the Tombs. Mr. J. D.'s condition was then, as it had been since being in jail, totally indifferent to his person and surroundings; the only voluntary movements were his eyelids and occasionally his lips: took no food or drink; he followed wherever led, and remained in the position in which he was placed. Food and water left with him were never disturbed: the attendants were positive that he could not swallow solid food, and gave him liquid food, which he swallowed in a mechanical way. Personal cleanliness was wanting and Nature's demands unattended, his clothing and bed being soiled without notice on his part. The attendants thought it unsafe to allow him to lie flat in bed for fear he would smother, and, as a precaution, braced him up with pillows in a half-reclining position, and they always found him as they left him, notwithstanding frequent observations were made; his eyes opened with the same staring expression. His indifference was such that, when being led through the cell door, which was low, he would strike his head terrific blows on the iron casing unless he was caused to stoop. He received several severe blows in this manner before being guarded against by the attendants.

With this history in brief Dr. Field first saw the case on December 18, 1887, and at frequent intervals afterward. When the patient was led into the examining room the keeper pushed him back and he sank down without resistance and remained in that position. He was tall and anæmic, had a fixed, staring expression, would not speak, or give any evidence of comprehending his situation or surroundings. He was neglected and careless in appearance. His pulse was small and quick; breathing shallow. Reflexes, superficial and deep, seemed normal. His limbs when raised sank back, as if from gravitation rather than from a paralytic condition. Cataleptic indications were negative. In the mean time two physicians had examined the case and reported to the district attorney that the patient was in a cataleptic or cataleptiform state and could not be tried. If Dr. Field stood in front of the man and threw water in his face or pricked the skin, no manifestation of feeling was made. When the same was done from behind, where the examiner could not be seen, involuntary movement followed. Severe pressure upon the supraorbital nerve gave no evidence of pain or anger, but caused suffusion of the face and a few tears to flow from the eyes. The pain inflicted was certainly as severe as one was justified in producing. Frequent interviews and various projects never induced him to speak. Dr. Field decided to photograph him, which he did twice. Owing to defective light, the exposure was about a minute and three quarters. No evidence of movement by the patient was manifest, to the astonishment of the photographer. I examined the photographs personally and they certainly were good. Even the eyelashes were as perfect as if portrayed by the delicate touch of an artist's brush. During his stay in the Tombs he became much emaciated, losing some forty pounds in weight. Dr. Field learned that J. D. had stolen a watch and escaped by rational effort. When arrested he pleaded not guilty and subscribed his signature. That night he was reported to have made an outcry and to have had a fit, after which he was as heretofore described.

*Personal History.*—At thirteen years of age he received a fall and was confined to bed five or six weeks. He had always

been "funny"—at times sulky and depressed, and at other times abnormally gay. Up to the time of arrest he was employed by his brother, who saw nothing strange in his actions. He was sentenced to prison three different times prior to this offense for felonious assault and larceny; his entire term of imprisonment extended over a period of nine years. When first arrested on the present charge he was rational and made offer to return the watch if they would not prosecute him. Relatives and prison officials were alarmed at his emaciation and were anxious to have his case settled, but, owing to the report of the two physicians to the district attorney that he was in a cataleptic condition and not fit to be tried, his case could not come up for trial. Dr. Field was firm in believing the man to be feigning, and asked that he be sent to Bellevue Hospital for observation; this they did not do, but instead sent him on December 29, 1887, to Jefferson Market prison, and he was there lost sight of. One morning the announcement in the paper was this: "The silent man departs." By the aid of one John Mack, on the night of February 5th, he sawed a bar out and escaped. Mack was recaptured, and from him Dr. Field learned that he and J. D. had been companionable for a month and that he kept watch for J. D. so as to allow him to exercise and get relaxation without detection, and that they frequently conversed together.\*

This certainly is as typical a case of deception as we are called upon to diagnose, but these are the very cases that teach us the value of observation. The majority of inexperienced observers in mental diseases would have made the same report in substance as did the two physicians who reported to the district attorney in this case and would have testified accordingly had the case come to trial; more especially would they have given the accused the benefit of their defective knowledge if there were a lawyer in charge of the case who understood the handling of lunacy cases and lost no opportunity in aiding the physician in getting his testimony in a presentable shape.

Again, there are persons unquestionably of unsound mind who are able to conceal the mental defects for a long time in many instances. The insane man will deny that he is insane, and when so able will conceal his eccentricities from those about him, as he is aware of their significance and the appreciation of the same by his friends. This peculiar deception is common in cases of paranoia, and often their delusions prompt them to the commission of murder in order that some imposed duty may be fulfilled. The manner of concealing their mental alienations from their friends is illustrated by the following well-known case which was on my service in the Amityville Asylum for two years: Miss —, about thirty-three years of age, was of great literary talent, and ranked high as a contributor to *Harper's*, *Scribner's*, and other popular magazines of the day. She conceived the idea of a lover, his going to sea, shipwrecked, and for a long time supposed to be lost. She learned of his rescue and return to New York. Through a conspiracy he was compelled to live under an assumed name, the name being that of a well-known correspondent of the *New York World*. This delusion grew till there were great numbers of conspirators in the scheme, and in the mean time she had decided some one must suffer death to clear up

\* Through the kindness of Dr. Field I am given this case in detail, for which I am under obligations to him.

everything; at times she thought she was the victim; at other times others were selected, owing to individual power of the conspirators. Her delusions were always systematized. This great deterioration went on for many months unknown and unobserved, until one Sunday morning a glowing article from her clever pen, covering nearly a page, appeared in the papers. Her ability to conceal her delusions finally failed. Fortunately the outbreak came in the form of a scandalous exposure rather than in murder. Prominent families were libeled and their good names stained with disgrace. Her own respected family never recovered from the shock, and it was only after prolonged efforts to compromise with the accused persons publicly excoriated in her defamatory article that they were saved from financial ruin arising from large damage suits. No compromise was acceptable except confinement in an asylum, and she was committed to Middletown under Dr. Talcott. Even there she was so acute in her deception that only learned alienists were aware of her true mental state. She would guard her subject, and, unless forced to speak upon it, no delusions could be obtained. For nearly two years I observed this case with interest, and in her delusions became an active conspirator. She continued to conceal her delusions well excepting at intervals, when she had to be restrained. Her vicious pen and ability to slip her notes to the public press were dreaded by those who knew her. Visitors at the asylum who talked with her believed in her rationality, and many sought to "show up" the asylum by carrying her writings to liberty. While on my service she wrote several interesting novels, as follows: *Was it a Delusion? The Model Boy of the Age; Hints to Friends on the Management of the Insane.*

Nine tenths of the readers of these novels would find them well written and of great interest, and rarely detect anything wrong in the writer's handling of the subject. In *Was it a Delusion?* a close observer who had known the author could detect a little something peculiar in the last four or five pages only.

These cases cited are simply representatives of the class of cases upon which medical men are called to render a decision as to whether the accused is or is not to be held accountable for his deeds and punished according to the provisions made by the law unto such cases, or whether he shall be cared for as an invalid as prescribed by the law of the State in which the crime was committed. You will observe in the Myer case before alluded to that neither one of these suggestions was carried out, but that he was allowed to go home and to liberty and to continue his homicidal acts as prompted by his delusions, and if he is an insane man he will certainly have his delusions at times. When the expert swears that in his opinion the subject before the bar is a malingerer, he assumes a great responsibility, and when he swears that the accused is of unsound mind and not accountable for his criminal acts, he also assumes a great responsibility; an error either way will give an excuse for the rendering of a dangerous verdict. Now, in the face of the argument given in the medico-legal blending of opinions, as to the mental state which may be classed under the nomenclature of the criminal insane, the

delicacy of making a scientific diagnosis in such cases and the great responsibility attached to the diagnosis made, I will allow you to ask yourselves this question, namely: Does the acceptance of expert testimony from the general practitioner in lunacy cases give rise to dangerous verdicts?

## DISEASES OF THE URINARY APPARATUS.

BY JOHN W. S. GOULEY, M. D.,

SURGEON TO BELLEVUE HOSPITAL.

(Continued from page 38.)

PART I.—PHLEGMASIC AFFECTIONS.

SECTION II.—SPECIAL CONSIDERATIONS.

### VIII.

#### URETHRITIS; ITS NATURE, CAUSES, AND DIAGNOSIS.

URETHRITIS, the most common of all the affections of the uro-genital apparatus, is a phlegmasic process, beginning generally in the mucous membrane of the urethra and ordinarily characterized by pain, ardor, dysuresis, and a more or less abundant muco-purulent discharge. In many cases it is contagious, but in the great majority it is non-contagious.

This phlegmasia was named urethritis, in the year 1802, by Bosquillon, because he regarded the word urethritis as expressing the locality and the phlegmasic character of the disease, and "gonorrhœa and blennorrhagia" as failing to convey the idea that the urethra is in a state of phlegmasia; the one meaning a flow of semen and the other a breaking forth of mucus. Therefore it was that he followed the example of Sauvages in the use of the suffix *itis* to denote phlegmasia, and accordingly constructed the word urethritis to express a correct idea of the nature and seat of the affection, *i. e.*, a phlegmasia of the urethra.

"*Gonorrhœa*" is the most ancient of the designations of this disease, and was used because of the supposition that the discharge was semen and originated in the seminal vesicles; and this erroneous designation is still used almost universally, although it is more than three centuries since urethritis was distinguished from the so-called gonorrhœa. In the sixteenth century Ambroise Paré spoke of gonorrhœa as an involuntary discharge of semen, and of *chaude-pisse* (clap) as a purulent discharge which he believed to originate in the seminal vesicles or, at least, in the prostatic region of the urethra. William Cockburn was the first English author to assert that "gonorrhœa" was seated in the urethral mucous membrane and not in the prostate or seminal vesicles. The first edition of his work, *On the Symptoms, Nature, Causes, and Cure of Gonorrhœa*, appeared in London in the year 1713, and the fifth edition in 1728. Many physicians who are acquainted with these facts still persist in speaking of the flow of pus in urethritis, in vulvitis, and in vaginitis, as "gonorrhœa," which means nothing more than a running of semen, because, they urge, the term has been sanctioned by long usage. Because an error has been reiterated for three thousand years or more assuredly does not make it less an error, and the long existence of this evil in language is certainly no argument in favor of

sanctioning its continual perpetration. Otherwise, how great would be the inconsistency of those who are striving to bring the science of medicine to its proper level in this nineteenth century of progress!

"*Blennorrhagia*," an outbreak of mucus, was first employed by the Austrian, Swediaur, in the latter part of the last century, in preference to "gonorrhœa," which, as he says, implies a flow of semen, while in reality nothing of the kind ever occurs in this disease. But the word "blennorrhagia" fails to indicate that the urethra is in a diseased condition. Even if the adjective urethral were always prefixed to "blennorrhagia," the two words would also fail to convey the idea of phlegmasia of the urethra. Although many different words have been proposed as substitutes for these two obviously inaccurate terms, the French still adhere to "blennorrhagia," which they originally borrowed from the eminent Austrian syphilographer.

"*Venereal catarrh*" is another expression now commonly used, in Germany and other countries, instead of "gonorrhœa." It was suggested in 1806 by Capuron, a Frenchman. Venereal catarrh of what particular part or mucous membrane of the body does not appear in the expression. But catarrh means simply a downward flow, not even a flow of mucus. Therefore catarrh fails to designate the true character of urethritis.

It is often asked, Is not "gonorrhœa, or blennorrhagia, or venereal catarrh" something more than a phlegmasic affection? Sometimes it is, and in that case there is urethral chancre, chancroids, or mucous patches—otherwise, "gonorrhœa, blennorrhagia, and venereal catarrh" have never conveyed to the mind of any thoughtful reader and investigator the faintest notion of phlegmasia, and to such the only meaning they express is a flow of semen in the first case, an outbreak of mucus in the second, and a downward flow from venery in the third case. It is asked also with equal frequency, Is there not high authority for saying that the terms "gonorrhœa, blennorrhagia, and venereal catarrh" should be applied to that form of disease which is contagious, and urethritis to that which is non-contagious? Yes, high authorities have made the assertion, without agreeing which of the first three terms should be used; but when high authorities misuse words there is no obligation to follow their bad example.

Many other names have been proposed to take the place of "gonorrhœa"; among them, *arsura*, *pyorrhœa*, and *syphiloïd*. The latter was used for a time by Ricord. None of these names had a long survival, for they were most unfit. But "gonorrhœa, blennorrhagia, and venereal catarrh" are, so far, examples of the survival of the unfittest. It is to be hoped that urethritis, answering as it does all present needs and indicating so clearly the phlegmasic character of the disease in the male, as do vulvitis and vaginitis in the female, may survive all those unfit names that always give a wrong impression if they convey any idea whatever. *Arsura* was spoken of by John Arden (1320 to 1370) as an interior heat with excoriation of the urethra, and he spoke of this same *arsura* as occurring in the genitalia of women. *Arsura* was also used as synonymous with *erysipelas*. The popular saying, "He was burnt" (meaning that he contract-

ed venereal disease), is likely to have originated from the old word *arsura*, which was apparently technical in the fourteenth century and coined from *ardere*, *arsum*, to burn, burnt.

The names given to urethral phlegmasia by the vulgar of several nations in some respects are more appropriate than those employed by the medical profession. These names, based upon different manifestations, are surely not worse than "gonorrhœa, blennorrhagia, or venereal catarrh." For example, the common people of England and of this country call urethritis *clap*, the French *chaudepisse*, the German *Tripper*, and the Spanish *purgación*.

*Clap* is derived from the old French *clapier*, which means a burrow, a hiding place, and is often applied by surgeons to burrowing abscesses. It means also a filthy place, a hovel, or brothel. The term *clap* may have been adopted on account of this meaning of *clapier*—a hovel or brothel where dwelt the women from whom the disease was supposed to be contracted, or perhaps on account of the filthy condition of the genitalia of these women.

*Chaudepisse* was suggested by the great scalding which is experienced in urination during the second or stage of increase of urethritis. For the milder cases the people use the terms *échauffement*, heating, and *coulante*, running.

*Tripper* is taken from *trip*, which means to drop or drip, and has reference to the dripping of the pus from the urethra.

*Purgación*, from *purgare*, *purgatum*, to cleanse, has reference to the abundant discharge, which the vulgar imagine "cleanses the system of a humor." It may also have reference to the fact that it is sometimes contracted from women during the menstrual period, for the people call the menses *purgaciones*, which they take literally from the Latin.

*Antiquity of Urethritis*.—There does not appear to be any historic period when urethritis was unknown. Dujardin and Peyrille, in the history of surgery from its origin to their day, speak of the great frequency of "gonorrhœa" in the East, and in alluding to the operation of "circumcision," which was employed partly to prevent venereal disease, trace the origin of this operation to a period antecedent to the time of Abraham. Moses very clearly points out "gonorrhœa" as existing in his time, and his sanitary laws tending to its prevention are admirable, and, if followed to the letter, would unquestionably lead very materially to the decrease of the disease. Hippocrates, Galen, and Celsus discourse upon this disease and its causes, and nearly all the medical writers of the middle ages make reference to urethritis.

THE NATURE OF URETHRITIS was long in dispute, and the question, Is it an infectious disease, a simple phlegmasic process, or a contagious affection *sui generis*? was earnestly discussed by able physicians, whose conclusions were so diverse that, for convenience, they were classed and designated as the identists and the non-identists. The identists were those who asserted that "gonorrhœa" and syphilis are identical diseases, *i. e.*, that "gonorrhœa" and chancres are produced by one and the same virus, and that "gonorrhœa" can produce chancres and *vice versa*. The early authors who

treated of syphilis were not identists—that is to say, they made a distinction between the “simple chancre,” the infecting chancre, and urethritis, and it was not until about the middle of the sixteenth century that the distinctions of these three diseases ceased, and that the doctrine of identism was promulgated by Musa Brasavola, of Ferrare, and generally accepted. This doctrine continued in vogue until the latter part of the eighteenth century, and was first questioned by Balfour (1767), then by Tode, of Copenhagen (1777), and by Fabre, a disciple of the renowned Petit, who showed that he had doubts upon the question of identism when he asserted that the consequences of “gonorrhœa” were not the same as those of chancre. The first edition of his work on venereal diseases was published in 1758. Hernandez, of Toulon, a surgeon of the French navy, published, in 1812, a monograph of 348 octavo pages to establish the non-identity of the “gonorrhœal and syphilitic viruses.”

The answer that may now be made to the question respecting the nature of urethritis accords with neither that of the identists nor that of the non-identists, which are so extreme, but includes all that seems rational from each side. *i. e.*, urethritis is, in all cases, a phlegmasic process. It is often contagious, but most frequently it is simple, non-contagious. It is contagious but non-infecting when it arises from urethral chancroids; it is styled virulent when it arises from the contagium of virulent vulvitis or vaginitis, and it is infecting when due to urethral chancres or mucous patches. It is not auto-inoculable when simple or when due to an infecting chancre. It is auto-inoculable when owing to a non-infecting chancre, called chaneroid by Clerc.

John Hunter was at the head of the identists, and Benjamin Bell ably and eloquently pleaded the cause of the non-identists. Hunter declared that “gonorrhœal” virus was capable of producing chancre and chanerous virus of producing “gonorrhœa.” The great master endeavored to settle this question in the month of May, 1767, by making an inoculation upon the prepuce and another upon the glans penis with pus taken from the urethra of a patient whom he believed to be affected with “gonorrhœa.” There resulted two chancres which were followed by constitutional syphilis. He therefore concluded that the two diseases proceeded from the same virus. A detailed account of this event with its ultimate result is given by Hunter in his treatise on *The Venereal Disease*, London, 1788, pp. 324–327. It now seems fair to assume that the urethral pus used in this experiment was the product of a syphilitic sore of the urethra.

Benjamin Bell took a diametrically opposite view of the subject, and, to overthrow the doctrine espoused by Hunter, made an elaborate and strong argument, abundantly illustrated by cases, in which his final conclusion was, that the pus of chancre could never produce “gonorrhœa” and that the pus of “gonorrhœa” could never produce chancre. This argument, contained in the first chapter of Bell’s work on *Gonorrhœa virulenta and lues venerea*, 1793, entitled the consideration of the question whether “gonorrhœa” and lues venerea originate from the same contagion, is well worthy of careful perusal by those who may wish to investigate the question.

Both eminent observers had their adherents, who warmly and ably argued the question which, many years after the death of the two contestants, continued to be discussed. It was finally settled by the concurrent labors of three earnest workers in this field of medicine—namely, Ricord, Bassereau, and Cullerier—but they shall now speak for themselves through the last named, who expresses their ideas substantially as follows: Ricord, who has made inoculations of venereal matter on the largest scale, has come to the conclusion that simple urethritis is never inoculable, that is to say, produces no specific sore, but that when a specific sore results from inoculation with urethral pus it is because there exists in the urethra a chancre which had escaped detection. But these observations, which at first sight seemed to throw such great light upon the question, have lost much of their value since the publication of the work of Bassereau, before which Ricord believed that chancre and syphilis were the same thing. From an exhaustive and conscientious clinical study of the subject, Bassereau was forced to conclude that all chancres were not of the same nature; that whenever there were syphilitic symptoms, these had been preceded by an indurated chancre; that the indurated chancre has always originated from another indurated chancre; and that a soft chancre has always been due to another soft chancre and never caused syphilis. Cullerier at first combated these ideas, as he had, though rarely, seen constitutional symptoms follow soft chancres; and it was not until the year 1857 that Ricord accepted the doctrine of Bassereau. In endeavoring to establish the differential characters of the two chancres, Ricord offered the following proposition: the soft chancre is inoculable for an indefinite period, while the indurated chancre can scarcely ever be inoculated—on the infected individual of course. This is a direct contradiction of his original proposition, which was to the effect that what distinguishes virulent urethritis, urethral chancre, from simple urethritis is that the former is inoculable, and that whenever the inoculation is negative in urethritis there is no syphilis. On the other hand, Ricord maintains that the indurated chancre alone gives syphilis and is rarely, if ever, auto-inoculable, and that the soft chancre has the property of being inoculated upon the sufferer. Therefore, says Cullerier, whenever an inoculation is made with the pus of urethritis, if this inoculation be successful, it is to be concluded that there exists in the urethra a soft chancre and that there will not follow any constitutional symptoms. If the inoculation is negative, this will afford no proof whatever that there will not follow constitutional symptoms, inasmuch as the indurated chancre rapidly loses its property of being inoculated.

From these statements of the case it is plain that what has been said of the value of inoculation to serve in distinguishing the two species of urethritis should be blotted out, or at least should be given another signification, for it is evident that the most inoculable is the least dangerous. The evidence furnished by inoculation is therefore not to be absolutely depended upon in the distinguishing of simple, chanerous, and chaneroid urethritis. The more rational and tenable position in regard to the nature of urethritis, so far as it is related to chancre and chaneroid—and this position

is based upon a careful analysis of the propositions of both the identists and non-identists and upon clinical observation—is that urethritis may be simple, or contagious, or it may be the consequence of a non-infecting, or of an infecting chancre, either of which being accidentally situated in the urethra, and acting, so far as the urethra is concerned, as a local irritant. The primary lesion of syphilis *per se* possesses no inherent property which, other than as a local irritant, may cause urethritis, the two diseases being entirely distinct. The same may be said of the third disease, the non-infecting chancre. From what precedes it may be concluded that a man can contract urethritis from a woman who has a chancre, chancroids, or mucous patches of the genitals. Many experienced and sound observers have encountered cases of urethritis so contracted, and the patients have not had the slightest indication of chancre or chancroids. Cullerier thus explains the phenomenon: In the primitive ulcer there are two things—a phlegmasiac product and something special; therefore the individual may take that only which is simply phlegmasiac and escape syphilitic or chancroidal infection, the pus acting only as an irritant. He quotes, from Benjamin Bell's work, the case of a medical student who placed some chancrous pus between the glans penis and prepuce, and this caused a simple balanoposthitis, while others, after introducing chancrous pus into the urethra, had only non-virulent urethritis.

It has happened that, from the same woman, a man has contracted a chancre on the glans penis, and nothing else, and that another man, almost immediately after, has only caught a simple urethritis. It has also happened that a man has contracted, from one woman, a "gonorrhœa," an infecting chancre, and non-infecting chancres; the woman being affected with all three diseases.

It may now be said that the proposition, contained in the answer to the question respecting the nature of urethritis, is sustained and may be summed up as follows: Urethritis may be non-contagious, it may be contagious and non-infecting, or it may be due to the presence in the urethra of an infecting or of a non-infecting chancre, and the same patient may contract a non-infecting urethritis simultaneously with a chancre or a chancroid in the urethra. This may have happened in the case cited by Hunter to prove the identity of the two diseases.

CAUSES.—Urethritis is said to be infecting when due to the presence of an infecting chancre or of a mucous patch in the urethra. It is non-infecting when owing to a urethral chancroid. It is named virulent when it arises from a contagium capable of reproducing itself indefinitely under proper conditions, as exemplified in the cases of urethritis commonly designated "gonorrhœa," contracted from virulent vulvitis or vaginitis, or by mediate contagion. It is called simple when non-contagious, whether originating from sexual commerce or from local irritants.

*Infecting urethritis is followed by distinct manifestations of syphilitic infection* in the course of from six weeks to three months. The physicians who judge from observation of the effect of chancre at the urinary meatus deny that urethritis is produced by urethral chancre, for in such cases

there is little if any tendency to the backward extension of the phlegmasiac action, which is commonly of short duration, and the mucous membrane of the urethra behind the sore remains intact. That a chancre seated within the urethra does produce urethritis was exemplified by John Hunter's well-known experiment. The urethritis caused by a urethral chancre, besides generally being slight and of short duration, is accompanied by little or no pain during urination. A case of urethritis which gets well, without treatment, in a week or in two weeks, needs to be viewed with suspicion and to be kept under close observation for at least three months.

The following is given in illustration of the clinical history of a case of infecting urethritis: The patient, finding it necessary to invoke medical assistance owing to certain symptoms which had caused him some anxiety, gave a part of this account of his complaint. Three months before he had contracted for the first time what he supposed to be an ordinary urethritis which gave him very little inconvenience and was well in a week. He had never had any other venereal disease. There was no visible sore or scar upon any part of his sexual organs. In the course of six weeks after the cessation of the urethral discharge he had a well-marked roseola, which was observed by a medical officer of the navy, and in six weeks more—that is, three months after the disappearance of the urethritis, when he applied for treatment—he was suffering from mucous patches in the fauces, and showed other unmistakable symptoms of syphilis. When this supposed simple urethritis began he was at sea (had sailed from New York several days before), and for the next eighty days was on board a man-of-war and in no way exposed to the contagion of syphilis. Assuming the veracity of the patient's story, it is fair to conclude that his urethritis was caused by an intra-urethral chancre.

*Urethritis due to mucous patches in the urethra*, though of rare occurrence, has been repeatedly verified by careful observers. It is characterized by a discharge which is at times sanious and which continues as long as the mucous patches exist. During urination there is some scalding pain. A patient who has never contracted urethritis, but after impure sexual commerce becomes infected with syphilis and, several months after the initial lesion, is affected with mucous patches in the fauces and a purulent sanious urethral discharge, may fairly be regarded as suffering from urethritis due to the existence of urethral mucous patches, provided that, in the mean time, he had abstained from sexual commerce.

*Non-infecting urethritis due to urethral chancroids* is not followed by lesions such as those which characterize the infecting, syphilitic variety, but it has its own special virus which acts locally and possesses the property of reproducing itself indefinitely in proper soils. The same observers who deny that urethral chancre produces urethritis also assert that chancroids do not give rise to this phlegmasia, and probably for the same alleged reason. That chancroids of the urethra do cause urethritis is a fact which few physicians now dispute. These chancroidal ulcers are prolific sources of cicatricial strictures in the fossa navicularis and even in the phallic region of the urethra. Chancroidal ure-

thrititis continues until the ulcer is healed and sometimes long after the healing process. The discharge is often profuse and sanious. When a doubt arises as to its nature, the question is decided by inoculating with it the patient.

By *virulent urethritis, improperly styled "gonorrhœa,"* is meant the urethritis resulting from sexual contact with a person suffering from a species of vaginitis or vulvitis characterized by a purulent discharge capable of reproducing itself, even when applied artificially to any of the mucous membranes that are susceptible to venereal phlegmasia.

*The mucous membranes which are most susceptible to venereal phlegmasia* are those of the glans penis, the prepuce, the urethra, the prostatic utricle, the urethral crypts, the anus, the mouth, and the conjunctiva.

*The mucous membranes which are refractory to venereal phlegmasia* are those of the ducts of the bulbo-urethral glands, the prostatic ducts, the ejaculatory ducts, the seminal vesicles, the spermatic canals, the bladder, the rectum, the nose, and the lacrymal canals.

Bonnières, who has compared the histological characters of these two groups of mucous membranes, describes the first as being supplied with papillæ and covered with pavement epithelium, with an underlying network of lymphatic capillaries whose parietes are constituted by epithelial cells, while the second group is covered by cylindrical epithelium with an underlying network of red blood-capillaries instead of lymphatics, and concludes that the venereal phlegmasia acts primarily upon the lymphatic capillaries and the epithelium, and that the phlegmasia of the neighboring tissues is only secondary thereto. In the prostatic region, for instance, there is a close subepithelial network of lymphatic capillaries which anastomose with the lymphatic capillaries of the spongy portion of the urethral mucous membrane and terminate abruptly at the urethro-vesical orifice, the bladder mucous membrane being entirely destitute of lymphatics; hence it is that the bladder is refractory to phlegmasia such as might otherwise be propagated through the urethra (Perrin).

THE NATURE OF THE CONTAGIUM OF URETHRITIS.—It has been asked what evidence is offered in support of the assertion that there is such an affection as a *sui-generis* virulent contagious urethritis? Many writers have endeavored to answer this question; among them, Dr. Thiry, of Brussels, and Mr. Hutchinson, of London.

Dr. Thiry enumerates three kinds of urethritis—the first, simple; the second, syphilitic; and the third, having a virus of its own which he calls the granulous virus, and which, he says, is the distinctive character of true contagious urethritis whose morbid elements are granulations. But granulations exist in the vagina and cervix uteri in many women who seldom give urethritis to men who are accustomed to lie with them or, to use Ricord's expression, whose genital organs are acclimated. This fact is undeniable, and overthrows Dr. Thiry's doctrine. If Dr. Thiry's views were correct, urethritis should be the rule and not the exception in these cases.

According to Mr. Hutchinson, the contact of dead pus, whose corpuscles are in an advanced state of fatty degenera-

tion, such as that from an abscess, causes but little irritation, while living pus, recently formed, is contagious and likely to cause phlegmasia when in contact with tissues similar in structure to those whence it originated. But this also fails to establish the character of the contagium said to be peculiar to non-infecting contagious urethritis. In accordance with the light thrown, of late years, upon phlegmasic processes, pus consists of dead leucocytes that have failed to destroy the morbid materials they have attacked; therefore there are no living pus-corpuscles. Pus is a dead substance to be ejected or encysted and rendered innocuous until transformed. That urethritis is often contagious is fully and frequently demonstrated clinically. A man affected with acute non-infecting virulent urethritis who deposits his urethral pus into the healthy vagina of a woman contaminates this vagina, and there follows vaginitis, and this same vaginitis causes urethritis in another man who exposes himself to the contagion. What, then, is the element of contagion, and where does it reside? Is it in the pus-cell, in the serum of the pus, or in the mucus contained in the morbid discharge? These questions have not yet been satisfactorily answered, although several theories have been advanced respecting the nature of the contagium, the latest being the microbial.

Among those who regard the contagium of urethritis as microbial is Dr. F. P. Jousseume, who, in his inaugural thesis on the vegetable parasites of man, Paris, 1862, describes an alga of urethritis, to which he gives the name of genitalia, and whose habitat, he says, is subepithelial. He believes urethritis, as well as vaginitis, to be caused by the presence of this parasite. This is here recorded only as a part of the history of the doctrines relating to the contagium of urethritis.

Many of the modern patho-histologists assert that in the discharge of simple urethritis no micro-organisms are present, while in non-infecting virulent urethritis, "gonorrhœa," the pus-cells contain a specific diplococcus, named "gonococcus," and discovered in the year 1879 by Neisser. It is further asserted that whenever this contaminated pus is conveyed to the urethra there follows a urethritis with the reproduction of the "gonococcus" in the pus-cells of the new urethritis.

Since the announcement of Neisser's discovery several other organisms have been detected in the pus of virulent urethritis. In some cases of virulent urethritis no "gonococci" have been found, while in many cases of non-virulent urethritis "gonococci" abound.

Diplococci undifferentiated morphically from "gonococci" have been seen repeatedly in pus from different parts of the body and in abscesses distant from the genital and urinary organs of patients in whom there were no traces of venereal disease.

It has been suggested that the contagium resides in the mucus of the urethral discharge, with the implication that this contagium may be a toxalbumin destructive to the epithelium. But whence this particular toxalbumin which selects the genitalia with such nefarious intent?

Since several different micro-organisms have been found in the pus of urethritis, may not any or all of these organ-

isms be capable of acting as irritants, and give rise to super-secretion of mucus, to blood stasis, plastic exudation, the emigration of leucocytes, and exfoliation of epithelium; some irritant being essential to the development of phlegmasia? Or is the irritant of urethritis likely to be a virulent ptomaine? This is certainly not impossible, since urethritis has been experimentally induced by the injection of dilute liquor ammoniæ.

Nothing so far discovered has sufficed to explain the nature of the contagium of that variety of urethritis mis-called "gonorrhœa."

By *mediate contagion* of urethritis is meant the transmission of the disease without coitus, but by contact with objects impregnated with the urethral or vaginal discharge of a diseased individual. The question of mediate contagion is of great consequence. Much ridicule has been cast upon it, and honest and veracious patients have often been discredited when they have declared that their urethral discharge was not the result of sexual commerce. Nevertheless, the possibility of contracting contagious urethritis mediately—that is to say, without sexual approach—is a fact which has been attested by excellent observers for a century past, and which was recognized even in the time of Moses, as indicated in Leviticus, chapter xv, verses 2, 3, and 4: "The man that hath an issue of seed shall be unclean . . . when a filthy humor, at every moment, cleaveth to his flesh and gathereth there. Every bed on which he sleepeth shall be unclean, and every place on which he sitteth." That patients contract purulent ophthalmia by using towels soiled by a person affected with contagious urethritis or vaginitis, or by the affected individual himself carrying a soiled hand to his eye, is of constant occurrence. What, then, is to prevent contagion if this pus be applied to the orifice of the urethra instead of the eye? That in these days patients do contract urethritis in unclean places without sexual contact is not a very uncommon occurrence, and that a healthy man sleeping in the same bed with a man suffering from contagious urethritis is liable to contract the disease is also a very reasonable assertion, as it is only necessary for an almost infinitesimal quantity of infected pus to make its way to the urethra to insure contagion, and contact with freshly soiled bed-linen during sleep is not unlikely. Nurses affected with contagious vaginitis or vulvitis have communicated purulent ophthalmia to infants in their charge entirely through soiled hands, and in the same way have given urethritis to children. Contagious urethritis engenders contagious vaginitis and *vice versa*. Such are among the ways in which the disease is propagated and perpetuated.

By *simple urethritis* is meant a phlegmasia which has no specific virus and is not contagious, but which arises from the action of mechanical or chemical irritants to the urethral mucous membrane, from sexual excesses, from masturbation, etc. It is characterized by symptoms similar to those of virulent urethritis. It has the peculiarity that the phlegmasic process often begins in the prostatic, membranous, or perineal region of the urethra, and gradually extends forward, and finally invades the whole canal, but it also frequently begins in the fossa navicularis, extends backward,

and is attended with nearly all the complications and sequels of the contagious form. In some cases there is much febrile reaction, and the discharge is very profuse; in other cases the urethritis is superacute, while in the majority it is subacute.

*Gouty patients are sometimes affected with a purulent urethral discharge*, which is often attended with scalding sensation during urination. This discharge usually disappears on the cessation of the gouty symptoms. In certain cases, however, the discharge lasts many weeks. Urethritis is frequently one of the first manifestations of an attack of gout, and thus shows itself each time the patient is newly attacked with "the gout." This occurs so commonly in some cases that the patients are able, two days before, to announce the advent of a gouty seizure, and they base their prediction upon the ardor urinæ, which they had noticed as so regularly preceding former attacks. The urine of these sufferers is loaded with uric-acid sand, and the ardor urinæ is caused by minute punctures inflicted upon the urethral mucous membrane in its whole extent by the sharp points of the uric-acid crystals. The mucous membrane thus wounded yields more or less blood, which passes away with the urine, and there soon follows a flow of pus which does not cease until the urine is free from crystalline matter. It sometimes happens that a number of uric-acid crystals are cemented together and form concretions of various sizes, from one to six millimetres in mean diameter, which, when carried along in the stream of urine, have been known to block up the urethra, cause retention of urine, and phlegmasia, and even ulceration of the urethral mucous membrane. Several such concretions have been found lodged behind urethral strictures, causing retention of urine, besides a copious purulent collection.

*Stone in the bladder, particularly the phosphatic, is sometimes an indirect cause of urethritis.* The ammoniacal urine, loaded, in such a case, with prismatic crystals, being extremely irritating to the urethral mucous membrane, at length causes a urethritis which, though subacute, is attended with inordinate sensitiveness of the canal.

*Urethritis is known to arise from the ingestion of substances which, being eliminated by the kidneys, render the urine acrid and irritating.* For example, the free and continuous use of asparagus as an article of food is not an uncommon cause of urethral phlegmasia. There are many persons who can not make use of this succulent delicacy for two or three consecutive days without being inconvenienced by a very considerable smarting sensation in the urethra during urination, and even by a purulent urethral discharge. Soon after eating asparagus, their urine emits a characteristic strong odor, and often contains innumerable crystals of oxalate of calcium, and this continues so long as they persist in indulging their desire for this luxury.

Among the many who have complained of the ill effects of asparagus is a young man who, during three consecutive summers, was annoyed by profuse urethral suppuration with much scalding in urination. On each occasion he believed himself affected with contagious urethritis, from which, however, he had never suffered, but during these periods he had been indulging very freely in asparagus. He was ad-

vised to abstain from this his favorite dish, and the discharge always ceased soon after his compliance with the advice.

*New ale, beer, cider, and other fermented liquors, even when used in moderation, are known to excite urethritis.* These beverages exert an evil influence upon the imperfect digestion of elderly men, and their use should be forbidden. The abuse of all alcoholic stimulants is a potent factor in the production of urethritis.

*Free doses of cantharides given ignorantly or with malicious intent* have led to the gravest consequences besides a free flow of pus from the urethra. Large Spanish-fly blisters applied to the trunk or extremities have been followed by the same ill effects.

*Urethritis may be due to any obstruction which favors stagnation and fermentation of urine in the bladder.* Those patients who have long suffered from obstructed urination caused by urethral stricture or prostatic enlargement, and, in consequence thereof, have been obliged to urinate with undue frequency, nearly all suffer from urethritis as a result of the great irritation produced by putrid, ammoniacal urine.

*Urethral phlegmasia is sometimes the outcome of frequent or of violent catheterism.* Sufferers from enlargement of the prostate, who are obliged to use the catheter four or five times daily to relieve their bladders, are, in the beginning, much inconvenienced by urethritis. In some cases the first catheterism excites an acute urethritis which renders subsequent catheterisms painful, but as it would be unwise to suspend the use of the instrument, measures are taken to mitigate the phlegmasia and relieve the pain, and they are ordinarily successful. Many cases could be cited where the first catheterism caused acute urethritis which, in a few days, yielded to rest and mild local treatment, and did not recur after the urethra had become habituated to the passage of the catheter. There are, however, many cases in which the urethral discharge becomes chronic and is maintained solely by the irritation to which the catheter gives rise, notwithstanding the most careful antiseptic precautions. In other cases, and unfortunately they are not few, the patients, from an unwise sense of economy, allow themselves to use worn-out, defective, or improperly constructed catheters, which seldom fail to cause local mischief. Others again, from carelessness or ignorance, use more or less violence, or catheterize themselves with undue frequency, and urethral phlegmasia, if not a more serious injury, is the almost invariable result.

When the external orifice of the urethra happens to be narrower than natural, and the patient is in the habit of catheterizing himself frequently and clumsily, there sometimes follows a phlegmasia of the extremity of the penis, with more or less induration, which renders the use of the instrument difficult and distressing. In a patient so affected, the induration had involved such a considerable portion of the glans penis that it was at first suspected to be of a malignant nature; but, after the more careful use of a smaller catheter and the local application of acetate of lead solution, the induration subsided, and the meatus was incised, so as to allow the easy passage of ordinary-sized catheters.

Exploring catheterism, even with a sterilized instrument, may cause urethritis. The following is a fair illustration of this point: A., sixty-five years of age, who applied for treatment on account of an attack of acute urethritis, with copious purulent discharge, and was not as frank and outspoken as a patient should be with his medical adviser, betrayed so much anxiety as to the probable cause of his ailment and asked questions of such character as to lead his hearer to the surmise that he might have exposed himself to contagion. However, after the summing up of a considerable amount of cross-questioning, this did not seem likely. At length it was incidentally learned that he had been catheterized, with due precaution, a few days before, with a view of discovering the cause of obstruction to urination, of which he had been complaining. The instrument did not penetrate the urethral canal more than two inches, and in two days the discharge of pus had begun. A cautious exploration revealed a very narrow stricture in the phallic region of the urethra, and the conclusion arrived at was that, if the patient had illicitly indulged his sexual desire, he surely had not contracted virulent urethritis, but that the acute phlegmasia was the result of the catheterism perhaps violently practiced upon an already diseased and sensitive urethra. The discharge ceased a few days after the urethra was properly enlarged.

*Foreign bodies of various kinds introduced from without into the urethra and retained for a certain length of time give rise to urethritis.* Among these foreign bodies may be mentioned broken ends of catheters or bougies, fragments of wood or straw, pudendal hairs, and many other objects. Several cases of urethritis caused by the accidental passage of pudendal hairs into the urethra have been observed, the purulent discharge ceasing soon after the removal of these foreign bodies from the fossa navicularis urethrae.

A catheter retained a few days in the urethra excites phlegmasia of the mucous membrane, and has been known to cause ulceration at certain points, such as the navicular fossa, the peno-scrotal junction, and the bulbo-membranous region, particularly in those cases of urethral stenosis treated by continuous dilatation where the instrument is sometimes unwisely retained a week or two weeks.

*Sexual excess appears to be the most common cause of urethral phlegmasia.* Fournier expresses the opinion that by excessive sexual indulgence men give themselves urethritis oftener than they receive it. He further asserts that seventy-five per cent. of all cases of urethritis are non-contagious. The majority of women from whom urethritis is supposed to have been contracted had not vaginitis or, at least, had not contagious vaginitis or vulvitis. The urethritis so developed is, of course, simple, non-contagious. There are women whose vulvar and vaginal secretions are so acrid as to give urethritis to all those that have sexual commerce with them. A case often quoted in illustration of this point is that of a noted and very attractive courtesan, whose genital organs were in a perfectly healthy state, but who, nevertheless, gave urethritis to all the men who won her favor.

*The occurrence of urethritis from sexual contact during immediately before, or too soon after, the menstrual flow, or*

during the early period of loehial discharges, has been very frequently verified, and such urethritis, although ordinarily mild, is often as obstinate as it is severe, and is sometimes followed by many of the evils of virulent urethritis, but it is never contagious.

*Urethritis is often caused by sexual contact with persons suffering from leucorrhœa, or from uterine cancer, or tuberculosis.* Excessive sexual indulgence with a woman affected with leucorrhœa is likely to cause urethritis in the man, who, when he discovers his infirmity, is too apt to accuse of infidelity his partner in the sexual debauch. This has frequently happened in the case of the newly married and has led to connubial infelicity, to much misery, to ill treatment of the innocent wife, to divorce, and to utter ruin. Other sad consequences, particularly to an oversensitive man who may have been suffering from an old gleet, are self-accusation, despondency, and perhaps even suicide, under the erroneous impression that he had infected his wife with a "disease of which he was not properly cured." It is almost needless to say that chronic urethritis is not contagious.

The following case illustrates another point of medical and legal interest. A medical man who had been under treatment for faucial diphtheria went away alone for a few months, and shortly after his return called to say that he had urethritis, from which he had never before suffered. In two weeks he was well without having had recourse to the ordinary internal treatment. The urethra was daily irrigated with mild astringent solutions, and a glass of Vichy water was taken thrice daily. It was ascertained that his wife had, at the time and long before, been suffering from leucorrhœa, and that such was the cause of the urethritis which had attacked the husband. In a year after this the wife went on a visit to her relatives in the country. On her return in three months her husband became affected with urethritis, and again on a third similar occasion. This last did not so rapidly yield to treatment, though it was milder than the first two attacks. The wife had so far refused to submit to treatment; at length, consenting, she was relieved of her local affection, and her husband never again contracted urethritis even after an absence of several months. A point of much interest in the case is that after recovery from each of the attacks of urethritis the patient had no trouble until the first sexual approach several months after a forced separation from his wife. The case corroborates the assertion of Ricord in regard to what he terms "acclimation" of the genitals.

That some men are less susceptible to urethritis than others is a fact which careful observers have repeatedly verified. Of two men, of the same age and of equally sound body, indulging themselves sexually, within two or three hours, with the same woman, untouched meanwhile by others, one has escaped unharmed while the other has contracted urethritis. In some instances it happens that the first becomes diseased; in other cases it is the second that becomes affected.

Men contract urethritis from women suffering from malignant or from tubercular ulceration of the cervix uteri. That women affected with ulcerated uterine epitheliomata, emitting acrid discharges, give urethritis to their husbands,

is a fact which bears the attestation of physicians of extensive experience. The discharge from tubercular ulceration of the uterus is not only capable of causing urethritis, but of producing tuberculosis of the urethra. Some cases of tuberculosis of the male genital organs have been traced to this cause.

*Masturbation as a cause of urethritis* requires more than a passing notice. Those addicted to the vice of masturbation are, in consequence, attacked with urethritis with greater frequency than is generally supposed. This urethritis usually has the characters of chronicity from the outset, and the discharge is so slight that it at first escapes observation, or otherwise it is thought to be of little consequence by the patient, the sensitiveness of whose urethra has perhaps been blunted by long-continued abuse; hence the many cases of stricture, the origin of which is not satisfactorily traced, except by those physicians whose attention has been fixed upon such cases and who have been able to extract the truth from patients regarding early habits of masturbation. The common story of these patients is that they had noticed a constant urethral discharge which they had regarded as diurnal emissions of semen. In rare cases this urethritis becomes acute and even superacute.

*Almost any sort of mechanical irritation of the urethra is likely to lead to phlegmasic action.* Infant boys sometimes suffer much from urethritis by being fingered by vicious nurses desiring to gratify their own depraved instincts, or, as they often pretend, "to prevent the child from crying." Young boys are not infrequently attacked with urethritis during dental evolution, or during affections which lead to errors in nutrition, the consequent hyperlithuria being the chief factor in the causation of the urethritis.

*Urethritis occurring in elderly men* is often a source of much anxiety and suffering. A question often asked is, To what extent are elderly men liable to urethral phlegmasia, and does this differ from the urethritis of youth; if so, in what particulars? This question may thus be answered: While urethritis is generally simple, non-contagious, among elderly men, and is less frequent than among young and middle-aged men, it can not be regarded as an infrequent affection in advanced life. For instance, it occurs to a greater or less extent in a very considerable proportion of cases of enlargement of the prostate, and of gravel and stone in the bladder. It is not denied that elderly men are sometimes affected with contagious urethritis, for some among them are so unwise as to expose themselves to contagion, but happily they are comparatively few, and those who commit sexual excesses are not many. Urethritis is generally not so violent in elderly men as in youth or middle life. Only very exceptionally is it severe in the acute type, and it is very rarely superacute. Most frequently it is subacute and soon passes into the chronic state. It is characterized by less pain, less ardor, less dysuresis, and generally less purulent discharge than in youth, but it is more persistent and less amenable to treatment. In youth, in the great majority of cases, urethritis begins in the anterior extremity of the urethra, while in advanced life it very often begins at the posterior extremity or at once invades the whole canal.

**DIAGNOSIS.**—For diagnostic, prognostic, and therapeutic purposes it is essential to bear in mind the following points: Contagious non-infecting urethritis, "gonorrhœa," and simple non-contagious urethritis may be benign, subacute, acute, or superacute, and may be primitive, in cases where the urethra was never before diseased, or secondary in cases where the urethra had been the seat of phlegmasia at some more or less remote time. Primitive contagious urethritis is said to incubate from four to seven or even fourteen days, while primitive simple urethritis has a very short period of incubation, and sometimes declares itself a few hours after the action of the irritant which has been its cause. Secondary urethritis, whether contagious or non-contagious, has also a very short period of incubation. Urethritis ordinarily begins in the balanic region and gradually extends backward, sometimes even to the vesical orifice.

The adjective *benign*, applied by some authors to urethritis, is intended to signify a type characterized by mild symptoms, such as a little ardor in urination, an itching sensation in the fossa navicularis, and a slight mucous discharge, all of which disappear in a few days. Though benign urethritis may thus rapidly resolve, it is frequently in reality the first stage, the close of the period of incubation of the other types. That is to say, what for three or four days may appear to be a simple benign urethritis may become a subacute, an acute, or a superacute urethritis, or the discharge may become slightly purulent and persist as a chronic urethritis.

*Subacute urethritis* is characterized by a free muco-purulent discharge with but little redness of the urinary meatus and slight scalding sensation in urination. Its periods of increase, stasis, and decline are sometimes all ill defined or scarcely perceptible. Resolution occurs in from four to five weeks, or the discharge lessens, but persists and becomes chronic.

*Acute urethritis*, as before stated, begins as benign urethritis, which is its first stage, lasting three or four days. After this the discharge becomes purulent and soon thickens into a creamy state, yellowish at first and later greenish from an admixture of blood; the phlegmasic action daily augmenting until about the tenth day, when it reaches its maximum of intensity. During this time there is much scalding in urination, the lips of the meatus are red and pouting, and nocturnal erections of the penis are frequent and painful. This is the second or stage of increase, which has been termed the acute stage of acute urethritis, the adjective acute having already been used to qualify the type of a phlegmasia. The acute type, for instance, has its stages of incubation, of increase, of stasis, and of decline. Then comes the third stage or static period, during which the phlegmasic process neither increases nor diminishes. This period may be short, lasting one or two days, or may last from seven to ten days. It is followed by the fourth or stage of decline, which is the beginning of resolution. The discharge is then thin and pale, ceasing ordinarily between the fourth and sixth week. Among young and healthy subjects the first acute urethritis often resolves within three weeks. In some cases resolution is incomplete and the dis-

charge persists indefinitely. The phlegmasia is then said to have passed into the chronic state.

*Superacute urethritis* is characterized by a superabundant flow of pus mixed with blood, all the other phenomena of acute urethritis being greatly intensified. There is often the complication of balano-posthitis with much œdema of the prepuce; the whole penis is swollen and the larger lymph vessels thereof are inflamed. Nocturnal erections of the penis are almost uncontrollable, extremely painful, and attended by what is commonly called chordee, which is a curvation of the distended penis toward the perinæum. This curvation is caused by a superabundant plastic exudation in the meshes of the submucous tissue and corpus spongiosum. The corpora cavernosa are gorged with blood, but, the corpus spongiosum being blocked by the exudate, complete erection of the penis is impossible. Retention of urine is of frequent occurrence in this type of urethritis. Resolution is generally incomplete, and the exudate becomes imperfectly organized, undergoes sclerosis, and stricture ensues.

*Chronic urethritis* is characterized by a slight mucopurulent discharge, often to the extent of a few drops only each day, but this discharge is persistent, and increases in quantity after a debauch or after sexual excess. Chronic urethritis is consequent upon any of the types to which reference has been made, or begins with the essential characters of chronic phlegmasia. Men suffering from chronic urethritis are much more liable to contract acute urethritis than those whose urethrae are sound.

*The site of the urethritis due to chancre*, mucous patches, or chancroids is the fossa navicularis, but in rare instances it has been discovered in the phallic and even in the perineal region of the urethra.

*Contagious non-infecting urethritis* begins in the fossa navicularis, and there remains stationary ordinarily for several days; then, if it do not speedily resolve, gradually extends itself as far as the sinus of the bulb, there to linger and become chronic, or on the third or even the fourth week may reach the urethro-vesical orifice, without, however, passing this limit—a fact which seems to justify the assertion that acute urethritis is a spreading angeioleucitis, terminating, as it does, abruptly at the neck of the bladder, beyond which no lymphatics have been discovered.

*Simple non-contagious urethritis*, like the contagious, often begins in the fossa navicularis and gradually extends backward, as was so well illustrated by Swedian's experiment. He injected into his own urethra some diluted liquor ammoniæ, and soon thereafter experienced the most excruciating pain, followed by an acute urethritis which behaved very much like acute contagious urethritis and lasted six weeks, beginning in the fossa navicularis and ending at the urethro-vesical orifice.

*As there are many exciting causes, so there are many varieties in the phenomena of urethritis.* The phlegmasia may be mild and transitory, or it may be mild and persistent. It may be violent and transitory, or it may be violent and persistent.

It may begin and end in the balanic and phallic regions,

or in the prostatic and perineal regions, or may invade the whole canal.

Its course may be benign or subacute for ten days or two weeks, and suddenly it may assume the characters of the acute or of the superacute type. As a general rule, this sudden change is provoked by some irregularity, such as a debauch, coition, etc., but sometimes the cause is not apparent.

The discharge throughout an attack of acute urethritis may be purulent and creamy, muco-purulent and glairy, thin and serous, or sanious.

An acute urethritis, at the expiration of four or five weeks, may seem to be cured, and in a week there may be a relapse, all the phlegmasiac phenomena returning. It may then again yield to treatment, and in a week or ten days after the cessation of the discharge a second recrudescence may occur, and this second may be followed by a third relapse. Thus, the phlegmasia may continue several months. In a case observed long ago it lasted one year. The patient, a medical man, from that time suffered with cystitis, of which he was not well fifteen years afterward.

(To be continued.)

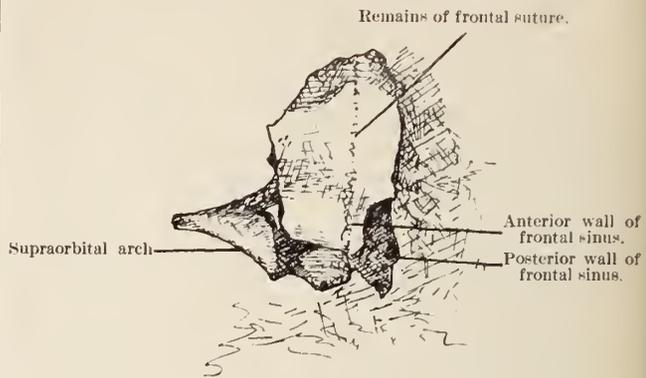

## A CASE OF COMPOUND DEPRESSED FRACTURE OF THE SKULL,

WITH VERY EXTENSIVE LACERATION OF THE BRAIN  
AND HÆMORRHAGE FROM THE SUPERIOR LONGITUDINAL SINUS.

By WALTER BENSEL, M. D.

L. L., aged thirty-eight years. Early in the evening of September 28th, while engaged in a bar-room brawl, patient was struck in the forehead with a heavy beer glass. He lost consciousness for a few moments only, and then recovered sufficiently to walk, unaided, to a police station, and was thence transferred to Bellevue Hospital in an ambulance. On admission to the hospital he seemed to be perfectly conscious, but was very nervous and irritable. His pulse was slow and full, pupils dilated, skin warm and dry, and respiration normal. Bleeding from the nose was slight, but there was such an extensive subconjunctival hæmorrhage on each side that the patient could only with difficulty close the eyelids. A wound about two inches long extended transversely across the middle of the forehead immediately above the supraorbital ridges. At the bottom of the wound could be made out a very extensive depressed fracture. The patient obstinately refused his consent to any operation until the next evening, when the subconjunctival hæmorrhage had become so great that it was impossible for him to close his eyelids over the protruding eyeballs. This caused him such pain and distress that he consented to an operation in the hope of being relieved. His temperature at this time was  $101.2^{\circ}$ , pulse was 78, but beginning to show the effect of the loss of blood from the epistaxis, which had continued steadily all day. As soon as possible after his consent had been obtained I operated, assisted by Dr. Gwathmey, Dr. Berkele, and Dr. Titterington. Anesthesia was obtained by chloroform. The skin in the neighborhood of the wound was thoroughly scrubbed with soap and water and then washed with alcohol, and finally with a solution of bichloride of mercury, 1 in 2,000. The hands of the operator and assistants were cleansed in the same way. The wound was then enlarged

and a careful examination of the fracture made. The depressed portion of bone, which is exceedingly well represented in the drawing (for which I am indebted to Mr. J. A. Bense),

Sketch showing actual size and shape of the depressed portion of bone which was removed.

was found to be almost completely detached from the surrounding bone and depressed for about half an inch, tearing the meninges very extensively. The removal of the detached bone was followed by a tremendous hæmorrhage from the superior longitudinal sinus. The hæmorrhage being too considerable to be controlled in the usual way by packing, I was obliged to think of some other expedient, and it then occurred to me to apply the principle of a lever. For this purpose I used the sliding catch of a Langenbeck artery clamp, which, it will be remembered, is a flat piece of steel about an inch and a half long, half an inch wide, and a sixteenth of an inch thick. One end of this catch I placed under the open end of the superior longitudinal sinus, *beneath* the edge of the opening in the skull; the middle of the catch rested *on* the edge of the opening, which formed the fulcrum of the lever; the other end of the catch, which projected out of the wound, I fastened firmly to the skin by two sutures. This controlled the hæmorrhage perfectly. On examining the frontal lobes of the brain, I found a laceration in the right, an inch and a half deep and half an inch wide, and one in the left nearly half an inch deep. I packed the wound very lightly with bichloride gauze (1 in 5,000) and dressed it with bichloride gauze (1 in 2,000), absorbent cotton, and bandages in the usual way.

At the end of forty-eight hours the dressings were removed. The metal catch had remained in place and checked the hæmorrhage completely. The bulging of the eyes was somewhat lessened, and there had been only slight epistaxis since the operation. The catch was carefully removed, and, no hæmorrhage following, the wound was packed lightly and dressed as before. From that time the patient made an uninterrupted recovery. The exophthalmos and pain in the eyes disappeared in a few days. There was no rise of temperature which amounted to anything during the whole convalescence.

SLOANE MATERNITY HOSPITAL.

**The Maximum Dose of Aconite.**—"It is reported in a recent case of accidental poisoning in Shoreditch that a woman died in four hours from the effects of a nine-minim dose of lin. aconite. This would equal about five grains of the root, or about one thirtieth of a grain of aconitine, which is said to have been the smallest quantity known to be fatal, the maximum dose of the tincture of aconite, B. P., being fifteen minims. Dr. Stevenson calls attention to the fact, and recommends that aconite should not be administered in full doses at less intervals than six hours. He has found that its local and constitutional effects do not disappear till after the lapse of from five to seven hours."—*British and Colonial Druggist.*

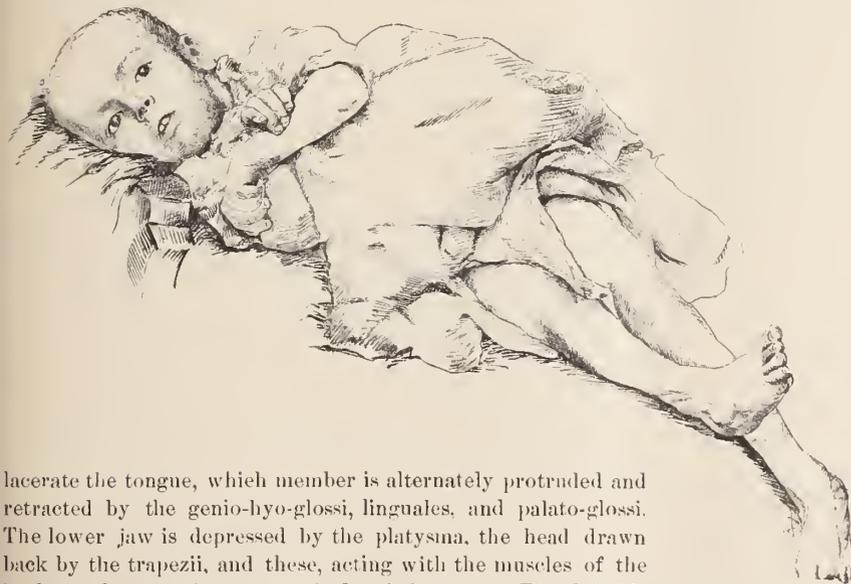

## A CASE OF GENERAL ATHETOSIS.

By HUGH HAGAN, M. D.,  
ATLANTA, GA.

Though authorities differ as to the correctness of designating athetosis a disease *per se*, yet we have sufficient authority so to do until it is otherwise decided. Taking advantage of this condition of affairs, I will, by your kind permission, ask space in your journal for the description of a case now under my care:

F. B. McL., aged four years, was of normal birth and healthy extraction. Up to nine months of age a healthy and well-formed boy. On Friday he was taken ill, and until the following Monday had continued convulsive attacks, marked by high temperature. The fever lasted five weeks, and during convalescence the mother noticed "the child moved constantly in all his joints." Further than this she could not describe his illness. She did not know the diagnosis, as the doctor only stated "the baby had fever." The child was brought to me over two years after the first illness, and having passed successively through the hands of numerous physicians, the most of whom pronounced it a chorea. I thought differently, and, after careful study during the past year, am still of the opinion that the condition is that of a general athetosis. After thorough trial of the bromides, iodides, arsenic, tonics, consisting of quinine, iron, cod-liver oil, cerebral and spinal galvanization, muscular faradization, the *status præsens* is as follows: The boy is in a state of constant motion. The movements are marked by that apparent volition and rhythm so different from the jerky, spasmodic character of the choreic. The eyes, though in a more or less constant state of movement, do not present the rapid vibratory character of a true nystagmus, but are more slowly and irregularly drawn up, down, in or out, as a result of the spasms of the external ocular muscles.

The masseters and temporals close the lower jaw so as to

lacerate the tongue, which member is alternately protruded and retracted by the genio-hyo-glossi, linguales, and palato-glossi. The lower jaw is depressed by the platysma, the head drawn back by the trapezii, and these, acting with the muscles of the back, produce at times a marked opisthotonos. The deltoids will bring the arms at right angles to the trunk. The triceps, biceps of both arms, the flexors, extensors, pronators, and supinators of the forearms, and the interossei and lumbricales of both hands, with their homologues in the thighs, legs, and feet, are at times in a state of extreme or partial contraction.

The laryngeal muscles are also affected, as the child has frequent "fits of holding his breath." The accompanying photo-

graphs give a very modified representation of his condition, as the photographer experienced great difficulty in obtaining even these. Further examination developed the following: After many attempts to examine the eyes, I am satisfied they are normal, especially the discs; further tests than the ophthalmoscope failed to give any evidence of faulty vision. The other special senses are normal.

The reflexes, both superficial and deep, though not as decided as in health, are quite marked, considering the marked muscular atrophy, or rather emaciation, which is due in a great measure to a lack of proper nutrition, as great difficulty is experienced in feeding him, his food being entirely fluid.

The electrical reactions are normal, the muscles responding to both the constant and faradaic currents. The lungs, heart, and abdominal viscera are normal and perform their functions. He had a phimosis which was remedied by circumcision. So great is the muscular inco-ordination that he can not sit or stand unassisted. He is totally ataxic aphasic, but, so far as his education will permit, I think not amnesic. Though not so accomplished as healthy children of his age, he is very intelligent. His cranium is of the brachycephalic type, with very prominent parietal bosses. The scalp is very tight, covered with a very scanty growth of hair, and the veins very prominent. The athetoid movements cease entirely during sleep, which is generally profound. When at rest the parts assume their normal physiological positions, no evidences of contraction or contracture being present.

Now, as to the cause of this condition I am at sea. Cerebral hemorrhage, embolism, abscess, or thrombosis, I think, we can exclude; but whether the boy's sickness was the prime or only the exciting cause I do not know. I am inclined to think, in spite of the pathological conditions generally enumerated—such as abscess or tubercle in the optic thalamus, the corpus striatum, the internal capsule, the cortex, or cerebral sclerosis or infantile cerebral hemi-

plegia—that the condition present is due either to a cerebellar tumor, in spite of the normal discs, or to meningeal adhesions over the motor cortical region, as I see no reason why these conditions could not produce the symptoms as well as those generally found. If the opportunity offers itself for a post-mortem I shall report the results.

211 PEACHTREE STREET.

## A CASE OF TRAUMATIC DEAFNESS.

### RECOVERY.

By W. H. BATES, M. D.

The chief interest of this case was in the recovery from symptoms of nerve deafness.

The patient, aged thirty-two, was the engineer of a construction train carrying a large quantity of dynamite. While traveling at a speed of about eight miles an hour the dynamite exploded. The effect of the explosion was tremendous. Besides wrecking the train, destroying the roadbed of the railroad, and killing many of the employees, houses two miles away had their windows broken, chimneys knocked down, etc. The accident occurred April 19, 1891. The patient was unconscious for a short time. He was able to arouse himself, however, and walk several miles to have his wounds dressed.

Sudden deafness with a bloody discharge from both ears occurred at the time of the accident. He also had a beating noise in both ears. He had a serous discharge from both ears the next day which continued and became slightly purulent. The quantity of discharge was never sufficient to run from the ears in a stream. He also had at times shooting pains through the head which were worse about five days after the accident. There was a scalp wound over the right ear four inches long.

May 28, 1891, began treatment. During the five weeks since the accident nothing had been done for his ears. The deafness had remained the same and the discharge had not decreased. The noise had increased somewhat. Both drum membranes were perforated, and the size of the perforations was about one half of the normal drum membrane. Both perforations were situated in the posterior inferior portion of the drum membrane; the lower end of the malleus handle was uncovered in each ear. The external auditory canals, which were large, were much excoriated. The discharge had a slight offensive odor. The hearing distance for the watch with the right ear was about one inch; for the left ear a little less. The tuning fork was heard better through the air than through the bone, and both aerial and bone conduction were better with the right ear than with the left ear. Aerial and bone conduction were diminished in both ears. Ordinary conversation was heard at about three feet.

After cleansing the middle ear, the deafness and tinnitus were not improved. Inflation improved the hearing for the watch about half an inch in both ears for a short time only; after a few minutes the hearing was the same as before inflation. The tests of the hearing with the tuning fork, together with the history of sudden deafness, seemed to indicate disease of the internal ear.

Treatment was first directed to healing the perforation of the drum membrane; later, such measures were employed as seemed to improve the hearing.

The patient was treated daily for about six weeks and then less frequently. He seemed still suffering from the effects of shock, although more than a month had passed after the accident. He was listless, easily tired, appetite poor, very drowsy all the time, with a dull feeling in his head. The drum mem-

branes showed no disposition to heal or the discharge from the ears to cease. His general condition resembled in some respects the constitutional weakness of diphtheria.

He began taking ten drops of tincture of iron in a goblet of water every half-hour through the day. The dose was increased rapidly and in a few days he was taking a teaspoonful of the strong tincture of iron every half-hour. The iron was well borne by the stomach. His appetite increased and became better than it had been before for years. His head became clearer and his general condition much improved. The drum membranes healed rapidly and the discharge from the ears stopped. These large doses of iron were taken for about a week.

With the improvement in his general condition the iron began to disagree, constipation being the first symptom. At the end of two weeks he could only take ten drops of iron three times daily. The patient also took laxatives when required. Laxatives seemed to lessen the tinnitus.

The local treatment of the drum membranes consisted in gentle syringing with hot water, and the instillation of peroxide of hydrogen into the external and middle ear.

Vaseline applied to the drum membranes seemed to act beneficially in the healing of the perforations and in stopping the discharge.

There was but little or no immediate improvement in the hearing or tinnitus from the use of local remedies in the middle ear; and after the discharge had stopped and the openings in the drum membranes had healed, the hearing was no better. The drum membranes were healed at the end of three weeks' treatment. Cotton worn in the external ears gave the patient great comfort in the presence of loud noises.

June 9, 1891.—The tuning fork was heard better through the bone than through the air. Both bone conduction and aerial conduction had increased, but the gain in bone conduction was much more than the gain in aerial conduction.

The hearing for the watch and conversation had not improved. Inflation produced more improvement in the hearing than at the beginning of treatment. Improvement temporary. Drum membranes still perforated. Discharge less. Tinnitus less.

The Eustachian tubes were open. Nares clear; some congestion. No discharge of mucus from the nose or throat.

Although there was very slight congestion of the nasopharynx, yet treatment to relieve this slight congestion produced very great improvement in the hearing and tinnitus. Cocaine in the nose lessened the noise and improved the hearing temporarily. The cocaine opened the nose more, and the drum membrane on the same side became at once less congested. This action of the cocaine was observed throughout the whole course of the treatment.

Nitrate of silver applied to the vault of the pharynx improved the hearing.

Politzeration during the early period of treatment, when there were symptoms of nerve deafness, produced very slight improvement in the hearing for a few minutes only. At times inflation had no effect.

Later, when the tuning fork was heard better by bone conduction than through the air, inflation produced more decided improvement in the hearing, and this improvement was more permanent. Occasionally inflation lowered the hearing temporarily, or produced no effect in one or both ears.

With increased aerial and bone conduction for the tuning fork, inflation produced the most marked and constant improvement. The hearing was improved more by inflation than by anything else.

June 20th.—The tuning fork was heard better through the air than through the bone. The watch was heard four inches

with either ear; inflation improved the hearing distance to twelve inches.

Several days ago the openings in the drum membranes had closed, the discharge had stopped, and the tinnitus had ceased.

Politzeration and treatment of the vault of the pharynx were continued until the hearing became normal.

August 15th.—Hearing normal for tuning fork, watch, and conversation.

December 1st.—Patient still has normal hearing.

#### Summary.

May 28th.—Symptoms of nerve deafness.

June 9th.—Symptoms of middle-ear deafness.

20th.—Symptoms during recovery from middle-ear deafness.

131 WEST FIFTY-SIXTH STREET.

**An Opportunity for a Medical Missionary.**—Two ladies, Mary and Margaret W. Leitch, who for seven years have been missionaries in Ceylon, have issued the following circular:

We are very desirous of finding a fully qualified physician to go as a medical missionary to Ceylon under the American Board. We would be truly grateful to you if you could direct us to any one who you think would be a suitable candidate. He should have had a good general and thorough medical education with some hospital or private practice. He should be a man of earnest piety who would consecrate his talents to the service of Christ. He should possess sound health and some executive ability, as the work which he will be called to do among 316,000 people in the northern province will be a large and important one. He should be a married man. We are hoping to find one who, with his wife, would be able to go to Ceylon at least by the end of this year. He would be expected to take up and extend the work of the late Samuel F. Green, M. D.—a missionary of the American Board for twenty-two years in Ceylon—who during the last years of his stay in that island treated, with the aid of his native assistants, as many as 10,000 patients a year. The salary of the doctor and his wife (\$1,200 a year, the salary usually paid to missionaries in Ceylon), also the amount required for outfit and passage, have been secured. In Ceylon there is a large, comfortable mission house ready for their use, also a dispensary, and a building for medical students; and the funds are now being pledged for the erection of a large hospital, the American Board having authorized us to secure \$10,000 for that object. There will be an income in the country from fees of paying patients and Government grant which will amount to over \$1,000 a year, which may be used in the conduct of the work. The endowment of ten beds in the hospital and of ten scholarships has been given or promised, also the sum of \$90,000 is promised, in legacies legally executed, toward a general endowment. There are at present eight missionary families in the province working in connection with the American and two English missions. There are about 3,000 native communicants in the churches of these missions and about 15,000 children in their mission schools. There are several higher educational institutions, girls' boarding schools, an industrial school, and a flourishing college. Tamil is the vernacular of the people, but the English language is becoming widely known. The field is an exceptionally attractive one, and the outlook hopeful, as the work has been successful among the higher castes, and it is believed these high-caste converts will take a share in the work of winning India to Christ. The ladies' address is No. 17 Lafayette Place, New York.

**Bequests to Hospitals.**—By the will of the late Mrs. Robert L. Stuart, of New York, the New York Cancer Hospital will receive \$25,000; the Hahnemann Hospital, \$10,000; the New York Ophthalmic Hospital, the Western Dispensary, the Dispensary of the Homœopathic Medical College, the Northern Dispensary, and the Northwestern Dispensary, \$5,000 each; and the Presbyterian Hospital, the New York Eye and Ear Infirmary, the Manhattan Eye and Ear Hospital, the Hospital for the Ruptured and Crippled, and the Woman's Hospital, each a large share from her estate.

THE

## NEW YORK MEDICAL JOURNAL,

*A Weekly Review of Medicine.*

Published by  
D APPLETON & Co.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JANUARY 16, 1892.

### ALBUMINURIA AND LIFE INSURANCE.

At a recent meeting of the Hunterian Society of London there was a discussion of the relations of albuminuria to life insurance. The *Medical Press and Circular* for December 9th contains an abstract of the debate. Dr. Hingston Fox opened the proceedings with a paper, which was commented upon by Dr. Pavy, Sir William Roberts, Mr. Clement Lucas, and others. Dr. Fox based his paper on his notes of the uranalysis in the cases of 282 applicants for life policies—all of whom were males except two. Albumin was found in thirty per cent. of the cases. This percentage depended on the fineness of the tests employed; coagulation by boiling was chiefly relied upon. The albuminuria of organic renal mischief was found in only eight cases out of the 86 of albuminous urine. Of another type, called "permanent albuminorrhœa," there were two cases; in one of these albumin was known to have been present at least two years, with apparently no disturbance of the health, while in a second case it was said that albumin had been observed from time to time during a period of seventeen years. The risk in such cases may be accepted under specially arranged terms, if the age is under forty, provided the diagnosis is clearly made out. Under the head of albuminuria from "loaded urine" the proportion of cases was very high, numbering 22 in 86. This might be called an albuminuria of "city life," or "civic albuminuria." Oxalate of calcium and uric acid are not infrequent in these cases, and glycosuria is more rarely an attendant symptom. This disorder is, as a rule, amenable to treatment, and if it passes away the applicant should not be rejected. Of cardiac albuminuria the ratio was as high as 20 in 86. The risk in these cases is to be judged apart from the uranalysis. Dr. Fox includes under this heading, to which he gives the name of "albuminuria of unstable circulation," both the functional and "cyclic" forms of this affection.

Dr. Pavy, who has been officially employed with insurance questions for many years, stated that he was a firm believer in the existence of a functional albuminuria which did not lead up to structural disease. Many cases of cyclic albuminuria were dependent upon the position of the body, and were not improperly styled "postural," the early morning excretion being usually free from albumin, which appeared in the middle of the day and was gone again at bed-time. An alteration in the mode of life will affect the amount of excreted albumin. Dr. Pavy is in the habit of requiring four specimens of urine—one passed at the rising hour, one at noon, one at 6 p. m., and the fourth at bed-time. If the patients are in bed during the day, the character of the urine is changed. As has been shown by Dr. Hingston Fox, these persons are known by their mobile disposition,

quick pulse, and irritable heart, with a sharp, "smacking" impulse. The albuminuric condition may continue long and then gradually wear away. It is bad practice to keep such patients in bed. These applicants are not to be accepted or rejected on the results of a first examination; they require investigation. Dr. Pavy instanced the case of a young collegian who studied his own condition to some profit. When a youth, aged eighteen, he was a good athlete and passed a civil-service examination, but subsequently, albumin having been found in his urine, it caused his rejection. The case was cyclic and he was afterward passed. He then went to Oxford, and from there went up for a final physical examination before going out to India. During this time he had read up the literature of these cyclic cases, and when the examination approached he remained in bed until just before the time, with the result that he was accepted, as there was then a temporary cessation of the albuminuria. Regarding the albuminuria that is associated with glycosuria, Dr. Pavy stated that the prognosis was usually favorable if the glycosuria was amenable to treatment; it did not lead on to Bright's disease, as had been taught by some of our recognized authorities.

Sir William Roberts defended the use of the term "physiological albuminuria." The time had gone by when the presence of albumin in the urine could be regarded as equivalent to a death-warrant. This condition might follow shock or strain, the passage of gravel, or the ingestion of a heavy meal. A child might run a race and come back flushed and with a thumping heart—symptoms that came within a physiological range; so, too, sharp exercise would cause a temporary albuminuria, which was not, in his opinion, outside of the physiological range. The same was true after the application of cold baths. In regard to the risks of these physiological groups of cases, and others that were only occasional and transient, there was no longer any occasion to pronounce a sinister prognosis, but the diagnosis must be definitely made out for the protection of the assurance companies. If the applicant was in early life, the prognosis was, of course, more favorable than in persons who had passed their fourth decade.

Mr. Clement Lucas referred to cases where there seemed to be a family predisposition to show albumin in the urine on slight provocation. These belonged to a non-hazardous class of insurers if properly treated. He had found albuminuria in men who, being about to be married, had applied for insurance, and the excitement incidental to these undertakings appeared to have the power to cause the disorder: in one such case, that of a man of thirty-four years, this symptom had caused the company to reject the application; after his marriage his urine was found to be entirely free from albumin, and he was to all appearances an eligible risk. Another instance of protracted ineligibility from this same cause is related by Dr. Sewill in the above-named journal. The patient is living to-day in his seventy-seventh year, although twenty-six years ago he had been shown to be markedly albuminuric by the late Dr. Sibson, of St. Mary's Hospital. The albumin was present in large quantity, and the causation of the attack was thought to be an un-

due indulgence in sea-bathing in chilly weather. The case was regarded as serious, and a careful regimen was prescribed. The patient, however, was scornful of medical opinion and did not follow directions implicitly. He had a good family history, and had always been healthy, fleshy, indolent, and a large flesh-eater, besides taking alcohol in moderate amount. In the course of four or five temporary illnesses in twenty years, albuminuria had been several times found, but the general health had not been seriously threatened until three years before, when an ascites and an abdominal abscess made their appearance. It was thought impossible that the man could recover, but he did. He is now hearty and scoffs at regimen and the wisdom of the faculty. Nearly all the physicians who at various times gave an unfavorable prognosis regarding the state of his kidneys are already under the sod. Assuming for the moment that this man was a rejected applicant for insurance, we can readily understand that an injury was done both to him and to the insuring corporation in consequence of the true value of his urinary symptoms having been misrated.

In conclusion, we can not do better than quote the following editorial opinion from the November issue of the *Canada Lancet*: "In placing an albuminuria in its proper place as regards ætiology, and in coming to a conclusion as to its probable effect upon the patient's future, the physician must take a wide survey of all the attending circumstances, and keep the patient for some time under close observation lest a serious error be made as to prognosis and treatment. There can be no doubt that hundreds of quite healthy persons are annually rejected by insurance companies because of transient and functional albuminuria, thereby entailing much worry and loss, not only upon the unsuccessful applicants, but also upon their families and friends." A greater amount of labor, care, and responsibility must be entailed upon the medical examiners in order to arrive at the true significance of urinary signs; but the same is true of every department of medicine that is not standing still.

### MINOR PARAGRAPHS.

#### TETANUS CURED WITH THE TETANUS ANTITOXINE.

In the *Centralblatt für Bakteriologie und Parasitenkunde* for December 22d, Dr. Rudolf Schwarz, assistant at the surgical clinic at Padua, gives the history of a case of traumatic tetanus, in a boy fifteen years old, cured by injections of the *antitossina del tetano* prepared by Tizzoni and Cattani from the blood serum of animals rendered proof against tetanus. He refers to another case treated by Gagliardi and, in a postscript, to two others treated by Pacini and Nicoladoni respectively. Tizzoni and Cattani's process is not given by Dr. Schwarz, but it is probably to be found described in their contributions to the *Riforma medica* during the year 1891.

#### THE PHILADELPHIA BOARD OF HEALTH AND LEPROSY.

This body, in conformity with the alarmist position it has maintained for some years past on the subject of leprosy, has adopted resolutions calling on Congress to establish stations for the treatment of persons afflicted with that disease. We do not

believe that Louisiana, that probably has more of such cases than any other State, will co-operate with this demand or perceive its necessity. Moreover, the number of cases of that disease in the United States does not justify such action by the General Government. Furthermore, it might be asked under what provision of our Constitution such patients could be confined in national lazarettos.

#### DISSECTING ROOMS FOR "THE OUTSIDE MAN."

Our vigorous young contemporary, the *New York Journal of Gynecology and Obstetrics*, calls for the renewal of an enterprise once successfully undertaken by the Brooklyn Surgical Society, that of establishing and maintaining rooms where anatomical study may be prosecuted without the necessity of one's enrolling himself as a pupil in any school. The opportunities at the schools and hospitals, says the *Journal*, are excellent, but confined to a favored few. "Give the outside man a chance," it adds. The idea is certainly praiseworthy, and we hope it may be realized.

#### THE ANNALS OF OPHTHALMOLOGY AND OTOTOLOGY.

This is the title of a new quarterly journal devoted to the subjects mentioned in its title, and furthermore, as the supplementary title informs us, to laryngology and rhinology. The *Annals* is edited by Dr. James P. Parker, and published in Kansas City. The first number, dated January, 1892, contains seventy-four octavo pages, devoted mostly to original communications. In its general appearance the *Annals* bears a striking resemblance to the *American Journal of the Medical Sciences*. We wish it as long and creditable a career as that journal has had.

#### PENTAL, A NEW ANÆSTHETIC.

PENTAL,  $C_8H_{10}$ , is a clear, colorless, thin neutral fluid with a peculiar sweetish odor and taste. Mering, according to the *Centralblatt für die gesammte Therapie*, finds that it has a distinct anæsthetic action without unpleasant after-effects. It has no appreciable influence on the pulse or respiration. It is easy of administration, patients coming under its influence in about four minutes without any of the unpleasant sensations produced by either chloroform or ether. For operations taking only a few minutes to perform, the author thinks that this new anæsthetic will fill all requirements.

#### IODOPYRINE.

The *British Medical Journal* for January 2d, referring to an article by Dr. E. Munzer, published in the *Prager medicinische Wochenschrift*, describes iodopyrine as a one-atom iodine substitution compound of antipyrine, occurring in colorless, tasteless, and odorless crystals, slightly soluble in cold water, but readily soluble in hot water. Its action is said to have been studied especially in typhoid fever and in pulmonary tuberculosis, in which it has shown itself an antipyretic of rapid action. In pulmonary tuberculosis it is reported as having caused profuse sweating.

#### THE ACTION OF CHLOROFORM ON BACTERIA.

The *Centralblatt für die gesammte Therapie* for December, 1891, contains an interesting article by von Kirehner on this subject. He has found that chloroform renders the spores of the anthrax, cholera, and typhus bacilli incapable of germinating and that pus germs are rapidly destroyed by this agent. He

thinks that this fact can be put to practical use in the treatment of these diseases, considering the diffusibility of the substance and its appearance in the stools and urine after its administration.

#### HYOSCYAMINE IN LETTUCE.

ACCORDING to the *Lancet*, Mr. T. S. Dymond recently read a paper before the Chemical Society in which he stated that he had found in the presence of hyoscyamine an explanation of the mydriatic action of extract of lettuce. The alkaloid was found in several varieties of the plant, in amounts varying from 0.001 to 0.02 per cent.

#### THE DOCTORS' WEEKLY.

THE first number of a new journal with this title was published on the 2d inst. Each number consists of eight large, four-column pages, containing reading matter and advertisements intermingled. Much of the former is chatty in character. Dr. Ferdinand King, of New York, is both the editor and the publisher.

#### THE MEDICAL FORTNIGHTLY.

This is a new journal published in St. Louis and edited by Dr. Bransford Lewis. The first number, dated January 1, 1892, contains forty-four large pages of reading matter. A novel feature is that a fac-simile of the author's signature is appended to each original communication.

#### THE BACILLUS OF INFLUENZA.

It is stated in the cable reports from Germany that Dr. Pfeiffer has discovered the bacillus of influenza, and has verified his discovery by inoculation experiments in six cases. It has been found both in the sputum and in the blood.

#### ITEMS, ETC.

**The late Surgeon W. H. Long.**—Surgeon W. H. Long, of the United States Marine-Hospital Service, died recently at Cincinnati. He was born in Kentucky in 1842, was educated in Louisville, and practiced his profession in that city until he was appointed an assistant surgeon in the Marine-Hospital Service in 1875; he was promoted to the rank of surgeon in 1878. During his service he was stationed at Louisville, Detroit, Chicago, and Cincinnati. At several of these stations he was connected with the local medical colleges, and was esteemed an able teacher of surgery. Several times he was a member of the examining board for the admission of candidates to the service. In many of the annual reports of the bureau he published professional papers. He was actively interested in the work of his profession, and was always a member of the medical societies of the State and city in which he was stationed, and several times was elected president of these bodies. His death will be regretted both by the officers of his corps and by his many friends in the profession throughout the country.

**The New York Ophthalmological Society.**—At the annual meeting held on Monday, January 11th, the following officers were elected; President, Dr. J. B. Emerson; vice-president, Dr. Gorham Bacon; secretary and treasurer, Dr. Frank N. Lewis; committee on admissions Dr. H. D. Noyes, Dr. A. Mathewson, and Dr. C. E. Hackley.

**The Death of Dr. Horatio S. Hendee**, of Lowville, N. Y., occurred on Tuesday, the 5th inst. He was graduated from the Castleton, Vt., Medical College in 1851, and served as surgeon of volunteers during two years of the civil war.

**The Death of Dr. Colin Mackenzie**, of New York, took place on Wednesday, the 6th inst. He was graduated from the Western Re-

serve University, Medical Department, in 1860, and was in his fifty-third year.

The Death of Dr. Joseph Hilton, of New York, took place on Thursday, the 7th inst. He was a licentiate of the Medical Society of the County of New York.

#### Society Meetings for the Coming Week:

MONDAY, *January 18th*: New York County Medical Association; New York Academy of Medicine (Section in Ophthalmology and Otolaryngology); Hartford, Conn., Medical Society; Chicago Medical Society.

TUESDAY, *January 19th*: New York Academy of Medicine (Section in General Medicine); New York Obstetrical Society (private); Medical Societies of the Counties of Franklin (annual), Kings (annual), Otsego (semi-annual—Cooperstown), and Westchester, N. Y.; Ogdensburgh, N. Y., Medical Association; Connecticut River Valley Medical Association (Bellows Falls, Vt.); Baltimore Academy of Medicine.

WEDNESDAY, *January 20th*: Northwestern Medical and Surgical Society of New York (private); New York Academy of Medicine (Section in Public Health and Hygiene); Medico-legal Society; Harlem Medical Association of the City of New York; New Jersey Academy of Medicine (Newark); Philadelphia County Medical Society.

THURSDAY, *January 21st*: New York Academy of Medicine; Brooklyn Surgical Society; New Bedford, Mass., Society for Medical Improvement (private).

FRIDAY, *January 22d*: Yorkville Medical Association (private); New York Society of German Physicians; New York Clinical Society (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

SATURDAY, *January 23d*: New York Medical and Surgical Society (private).

#### Answers to Correspondents:

No. 369.—The practice is contrary to the letter of the code of ethics, but it is tolerated in some parts of the country. We should advise you not to adopt it.

## Letters to the Editor.

### QUANTITATIVE TESTS FOR UREA.

BROOKLYN, *January 2, 1892.*

To the Editor of the *New York Medical Journal*:

SIR: In the *Journal* for November 21st, page 571, Dr. J. C. Bierwirth makes some remarks upon a method of estimating urea in urine devised by myself, which I desire space in your columns to correct. He states in one place that the results by this method are too high, and in another he states that he obtained with the solution I employ only 1.65 per cent. of the true amount of urea.

I was surprised to see these remarks in print, as I had pointed out to him the errors in manipulation at the time his paper was read. He did not work according to the directions, because he compressed the air in the tube by forcing into the open end of the tube a tightly fitting cork, and read the height of the column of liquid under this pressure. The second reading he made at the atmospheric pressure. Any one who knows anything of the properties of gases can see that this method can not give the amount of nitrogen evolved during the effervescence. The results will vary with the pressure used in forcing in the cork. In a demonstration of the method of using the apparatus before the meeting, Dr. Bierwirth himself obtained the theoretical amount of nitrogen from a standard solution of urea, after

making allowance for the compression by the cork. His second error of manipulation was in not thoroughly mixing the urine and the reagent. His tests made at the Hoagland Laboratory, with the solution I have proposed, were made with the apparatus of Dr. Doremus, which does not allow of thorough mixing of the urine with the reagent, and consequently the long time required and the incomplete reaction. In regard to the objection to the use of the thumb to close the open end of the ureometer, I have only this to say: I have used the apparatus for about two years and have taught students the use of it, and have not found any such difficulty as he mentions. After repeated trials by myself, my assistants, students, and others, including Professor Van Cott, whom Dr. Bierwirth mentions, I must affirm that this apparatus and solution, when used with reasonable regard for directions, do give as accurate results as any method mentioned in the article in question. It is more rapid, simpler, and more agreeable to operate than any other method with which I am acquainted. It is inexcusable for the author to have published his blunders after having them pointed out to him.

E. H. BARTLEY, M. D.

BROOKLYN, *January 8, 1892.*

To the Editor of the *New York Medical Journal*:

SIR: It is with surprise that I read a statement published November 1, 1891, in your journal, in Dr. Bierwirth's paper on Quantitative Tests for Urea, regarding the use of a solution of potassium bromide in chlorinated soda. The doctor states that with this solution he only gets from a two-per-cent. solution of urea 1.65 per cent.; that "this has been verified by Dr. J. M. Van Cott, Jr., at the Hoagland Laboratory."

I was present at the meeting of the Kings County Medical Association when the doctor read his paper. In the discussion which followed his reading I admitted that this was so, but pointed out the fact that our failure to obtain the theoretical amount of urea was due to failure to thoroughly mix the solutions.

Furthermore, I saw the doctor at this meeting repeat the test with this solution, and obtain the exact theoretical amount of urea after thorough mixing of the liquids. This was accomplished in Dr. Bartley's tube. At the time I suggested that similar results might be obtained with the Doremus bulb if the liquids could be thoroughly mixed; and since then I have verified this supposition by actual experiment.

In view of these facts, the doctor had no authority to use my name as he has in the publication of his paper, and I shall be greatly obliged to you for correcting the matter in your journal.

JOSHUA M. VAN COTT, JR.

### SHALL SUCCESS IN THERAPEUTICS BE IMPERILED BY ETHICAL CONSIDERATIONS?

WASHINGTON, D. C., *January 13, 1892.*

To the Editor of the *New York Medical Journal*:

SIR: I have read and weighed the contents of the letter in your issue of December 19, 1891, on this subject: Shall Success in Therapeutics be imperiled by Ethical Considerations? That certain points in this letter have made a profound impression upon me is the main reason why I now address you, and respectfully ask that my letter be published in the columns of the *Journal* in vindication of the honorable standing to which all good and true practitioners of medicine aspire.

Dr. Dodge states very clearly a point that is now appealing to every progressive physician—that in these days of advancement in the manufacture of pharmaceutical products we should no longer be confined, as were our forefathers, to prescribing drugs in their crude form, since there are to-day thoroughly at-

tested remedies in palatable form which our patients can take without repugnance and with benefit.

Now, while the code of ethics is an admirable exponent of the tenets which are acceptable to the great body of practitioners in our country, yet it is at least a question open to discussion whether there are not some points which in our progressive age might be reconsidered and revised. And I would suggest as one subject for discussion the question of the approbation and recommendation of certain proprietary articles which are in almost daily use by very many of our ablest practitioners.

Why should those preparations be condemned simply because their manufacturers are protected under a registered trademark? Is it not perfectly legitimate for our medical societies to elect competent committees to be judges of the therapeutical value of tried proprietary preparations? And could not their recommendation also be secured by their indorsement—

1. In didactic and clinical lectures and private instruction given to medical students;
2. In original articles acceptable to the editors of recognized medical journals; and
3. In standard medical works?

I address you particularly on this subject for the reason that the readers of your journal have carefully observed the fearless manner in which you and your able associates have detented the worthy against the unworthy and given justice where justice was due. We have also seen that your journal has reviewed and commended works by others than medical writers. I have in mind the fact that the very excellent work on the therapeutical application of coca erythroxyton by Angelo Mariani, of Paris, France, the proprietor of the world-renowned *Vin Mariani*, was favorably reviewed in your journal.

WILLIAM H. HAWKES, M. D.

## Proceedings of Societies.

### NEW YORK ACADEMY OF MEDICINE.

*Meeting of December 3, 1891.*

The President, Dr. ALFRED L. LOOMIS, in the Chair.

**Drainage of the Uterus in Chronic Endometritis and Metritis, with and without Salpingitis.**—Dr. W. M. POLK read a paper with this title. As drainage of the uterus was a surgical procedure that at present was pretty well recognized, the author confined himself to a description of his cases and the details of his method of applying the principle. The operation of vaginal hysterectomy—which, if called for, could be done with impunity—had been the means of inciting him to attempt invasion of the interior of the uterus in the treatment of diseases of that organ. The only class of cases to which the method of drainage was applied were those of chronic conditions, such as fungous or hæmorrhagic endometritis and metritis due to subinvolution. The most obstinate cases were those of endometritis due to flexions. Those cases which yielded most readily to the treatment were metritis consequent upon subinvolution. From his experience he was obliged to differ with previous observers, whose statements were to the effect that salpingitis and circumuterine inflammations precluded intra-uterine treatment. He advised the early treatment of endometritis and metritis by drainage, to prevent the extension of the disease to the tubes. As to the remote and permanent results of the operation, seven months to a year had elapsed since treatment in a large number of cases, and there had been

no return of the trouble. Immediately after the operation there was usually a slight rise of temperature, but it gradually returned to normal, the patient, with this exception, suffering no inconvenience. In some cases where perimetrial masses had existed prior to the operation these were in two or three weeks after treatment found to have become softened and in some instances abolished. In no case was inflammation set up by the manipulation or by the presence of the packing. The author reported in detail the histories of a number of cases to illustrate the success of his method. In four of these, laparotomy had been the primary operation, and, the appendages not requiring removal and endometritis being found present, the author had not hesitated to pack the uterus with gauze at the same sitting. The requirements for the method were as follows: 1. Antiseptics, bichloride solutions (1 to 500 and 1 to 2,000). 2. Strips of sterilized gauze about a quarter of an inch in width and three feet long, from six to eight thicknesses to be used at a time. 3. A large cervical speculum with a plug. 4. Forceps, a volsella, and dressing forceps. 5. A Sims speculum. 6. A good dilator. 7. A sharp curette. 8. A long-handled screw. 9. A fountain syringe and a glass tube. He preferred, as a rule, general anaesthesia, as the operation was more or less painful, although in twenty-five per cent. of cases the os was sufficiently patent to allow of local anaesthesia being used if desired. The next step was to cleanse the parts with soap and water, and finally with the bichloride. After dilating the uterus it was irrigated and the sharp curette thoroughly used. As to the amount of tissue to be removed, one must be governed by the individual conditions of the case. Following the curetting, irrigation was again performed. The gauze was placed in the 1-to-500 bichloride solution, and taken out and rinsed in hot water, the excess of which was squeezed out and the gauze then packed in the uterus by means of the long-handled screw. The patient was then put to bed, to remain there for about a week. At the end of that time the packing was to be removed, if it had not been forced out in the mean time by the contractions of the uterus. The uterus was then irrigated and the patient allowed to go about her usual vocations. As a rule, but one application of the packing was necessary to cure the most obstinate case of chronic endometritis or metritis.

Dr. W. T. LUSK had had no personal experience in the method described by Dr. Polk, but he had been an ardent advocate of the principle of drainage, and intended henceforth to try and carry out some such plan as that brought forward by the author of the paper.

Dr. C. C. LEE had never carried out the plan of Dr. Polk, but had used a method of his own for drainage of the uterus after removal of fibromata and retained placenta. This had consisted of the retention in the uterine canal of a tube which allowed of free drainage. This tube was frequently left *in situ* for ten days and more, and, while giving free exit to discharges, often corrected flexions and cured dysmenorrhœa. Another point was that the speaker never used bichloride solution in the uterus; he preferred hot water for irrigation. He had used his plan in forty-two cases with very satisfactory results.

Dr. W. G. WYLIE said that Dr. Polk must be laboring under a mistake when he referred to drainage of the uterus as a principle only recently recognized. While it might be true that drainage by means of gauze was something new, drainage as a principle had been written about and understood as practicable almost twenty years ago, and for the past eight years had been taught at the New York Polyclinic, and was being carried out by many of the younger gynæcologists. As to the value of Dr. Polk's particular method, the speaker thought that the use of so large a cervical speculum was impracticable in the majority of cases; that, as a rule, in cases of dysmenorrhœa there was imper-

fect development; and dilatation to the extent that would allow of the speculum being admitted and the uterus packed would split that organ. The speaker had found that dilatation of the uterus for half an inch frequently caused rupture. For the purpose of drainage it was his practice to use a hard rubber bulbous tube with the opening one third of its caliber; this was retained securely in the uterus and allowed of free drainage. Where there was pus or inflammation in or around the tubes he considered almost any manipulation within the uterus dangerous. As to curetting, this he would never do in the case of large soft uteri from subinvolution, as perforation of the walls was liable to occur, until he had reduced the uterus with boro-glyceride tampons. In some cases of hardened uteri, with fibrous conditions, it was a difficult matter to say what was the best method of treatment, as he had found, no matter what plan he had pursued, the condition would return sooner or later. As to drainage, he had long been an advocate of the principle.

Dr. G. M. EDEBOILS thought that as a principle all recognized the necessity of drainage in uterine diseases. He was convinced that as yet nothing so practical as Dr. Polk's method had been suggested, and he, for one, would give it a fair trial, although he would confine his cases for such operation to those where disease of the tubes could be excluded. Where the disease was restricted to the endometrium, curetting and drainage were called for. He reported the cure of three cases of pyosalpinx, occurring in young girls, with repeated attacks of pelvic peritonitis, by the introduction and retention for three months of the Outerbridge speculum.

Dr. F. KRUG had often wondered why it was that gynecologists had hesitated to attack the purulent uterus on surgical principles as they would any other pus cavity. It was his practice to use iodoform gauze for intra uterine packing, a method he had had no reason to regret, as his results were uniformly good.

Dr. T. ADDIS EMMET thought that his previous work bore testimony to his early recognition of the principle of drainage in his practice of dilatation of the uterus with sponge tents and irrigation with hot water. Drainage was certainly a good thing where the tubes contained pus, but doubtless Nature cured a good many of these cases. As for the diseases called metritis and endometritis, he would be glad if some one would demonstrate to him what was understood by these terms, as he had never seen a case in the autopsy room. In a woman that was menstruating there was no true mucous membrane lining the uterus, the tissues being in a constant state of transition. If the parts were diseased the trouble was generally confined to the cervix. For the last ten or twelve years he had never introduced a probe into the uterus, as a matter of routine, recognizing the fact that as a rule discharge from that organ was a symptom of disease lying outside of the uterus—such as pelvic inflammations or growths, which could be diagnosed as such. He had never seen a case in all his practice where a woman who had never borne a child required treatment of the interior of the uterus. He thought, however, that Dr. Polk's method had a field, but it must not be forgotten that discharge from the uterus was a symptom and not a disease.

SECTION IN OBSTETRICS AND GYNECOLOGY.

*Meeting of December 16, 1891.*

Dr. EGBERT H. GRANDIN in the Chair.

**Osteoma of the Ovary.**—Dr. H. C. COE presented such a specimen taken from a woman, thirty years of age, who had suffered for years with excruciating pain in the ovary and finally a rise of temperature. On removal, the ovary was found to have undergone bony degeneration, without very much enlargement.

The pressure, however, of the bony mass must have caused the severe pain.

**Angeioma of the Liver.**—Dr. H. T. HANKS related the history of a case in which he had made an exploratory incision into a tumor evidently proceeding from the lower lobe of the liver, but there was an uncertainty as to what the growth really was. The incision revealed what seemed to be a cancerous growth of the entire lower lobe of the liver, which extended quite a distance beyond the median line and reached down to the pelvis. The line of demarcation between the healthy and diseased tissue was distinct, but, as nothing could be done, the wound was closed and the patient allowed to recover from the operation, when a course of electricity was tried. Puncture was performed twice, but the patient seemed not to endure it very well, so that the simple application of the current, with compression with sponges, was continued. It was now several months since the exploration was made, and the patient was in much better health and was able to go about and do her work, the tumor having lessened about two thirds in size.

Several cases of angeioma of the liver had been reported where the patients had got well without treatment, so that he could not be sure that the electricity had been the cause of the improvement. If anything had done good, it was the compression of the sponges, which had been pressed upon the tumor pretty firmly.

Dr. G. M. EDEBOILS was able to report recovery in such a case where he had instituted no electrical treatment. He thought that the compression of the liver in Dr. Hanks's case might have had something to do with the improvement.

**Expectant Treatment of Intraligamentous Rupture of an Ectopic Gestation Sac.**—Dr. G. W. JARMAN read a paper on this subject. He said that, although most writers were agreed as regarded the main points of diagnosis and treatment in such cases, yet not a few seemed to have confusing ideas on the following points: 1. The causation and pathology of rupture. 2. The cause of hæmorrhage after rupture. 3. The diagnosis between intraperitoneal and extraperitoneal rupture. 4. What patients should be operated upon and what only treated otherwise. Pretty much all agreed that the majority of cases occurred either in women who had never previously borne children or else in those who had had quite an interim since the preceding pregnancy. That this was due to a diseased condition of some of the reproductive organs seemed most probable. Recognizing the fact that the mucous membrane of the tube was of the ciliated-columnar variety, with cilia, which in health had a constant waving motion toward the uterine cavity, but were rapidly destroyed by disease, it seemed also probable that the tube, no longer guarded, might become invaded by the spermatozoid and be compelled to domicile it. Added to this, there was the existence of bands of adhesions constricting the caliber of the tube at some point, and we found no slight difficulties which the ovum must overcome if it reached its proper destination. If it should become adherent to the tube wall, it either died or else continued to develop so long as its surroundings would permit. Undoubtedly the torn arteries and veins had a share in the production of the hæmorrhage, but, from the quantity found in this class of cases after rupture, it had seemed most probable that the opened sinuses played the greatest part. The study of the course of the hæmorrhage when it had broken into the broad ligament necessitated the study of the arrangement of the pelvic peritonæum. The diagnosis between an intraperitoneal and extraperitoneal rupture should not present marked difficulties. The fact that in the former the hæmorrhage was into a free cavity, while in the latter it was necessarily limited, should give a marked difference in the degree of symptoms. Another increment to the severity

of the symptoms was due to the shock attending the introduction of a foreign substance into the peritoneal cavity. The tumor which had ruptured into the peritoneal cavity was usually situated in the *cul-de-sac*. In the extraperitoneal rupture, the tense elastic broad ligament could be felt bulging into the vagina and in most instances the uterus would be pushed toward the opposite side. If the hæmorrhage had been extensive, the mass could be palpated through the abdominal wall. The diagnosis between cases of rupture into the broad ligament and those of broad-ligament hæmatoma would offer more difficulties. The question would at once arise, Did such a thing as a simple hæmatoma ever exist, or was it simply a term handed down from the time when but little was known of ectopic gestations and their frequency? Why should the veins of the broad ligament be less susceptible of dilatation than those of other parts of the body? And, above all, why should we not be able to find an occasional rupture in the veins of the pampiniform plexus in the male where we knew the varicose condition was so much more frequent? The expectant treatment, as the term implied, consisted in the readiness on the part of the physician to meet any indications which might arise. Hæmorrhage either had ceased or else would cease as soon as the resistance equaled the propelling force. The author had been unable to find any case reported in which this extraperitoneal hæmorrhage had caused death. If the anæmia became alarming and the life of the patient was in actual jeopardy, then, of course, a laparotomy would be indicated and the bleeding point sought. The patients should be forced to remain in the recumbent posture; aside from this and looking after the general functions, but little could be done. In the after-conduct of the case, should symptoms of sepsis supervene, the most rational treatment would be the early evacuation and drainage of the cavity. In case the life of the fœtus was not destroyed at the time of the rupture, but it continued to develop, another indication for treatment presented itself. The great principle was to operate when it was safest for the mother without regard to fœtal life.

Dr. COE thought that the danger of an extraperitoneal hæmorrhage becoming intraperitoneal was slight. He had seen as much as two or three pints of blood between the broad ligament, where it had dissected up behind the peritonæum, but had never seen a secondary rupture.

Dr. HANKS also doubted if there was any danger of secondary rupture into the peritoneal cavity. He advised the expectant treatment. In a number of cases he had been gratified by good results under the expectant plan. He thought that irregularity in the type of menstruation was a good point in diagnosis. This should always be inquired into. As to the amount of hæmorrhage, it was not surprising that it was so profuse when it was taken into consideration what a vascular organ the uterus was during gestation.

Dr. JARMAN did not think that this reason accounted for the amount of blood which escaped in rupture of an ectopic gestation sac of only a few weeks' growth. He felt satisfied that it came from the sinuses and that it was not arterial blood.

**Suppurative Oophoritis.**—Dr. H. J. BOLDT read a paper with this title. Abscesses within thickened, inflamed, and hyperplastic masses of the pelvic peritonæum, more especially the broad ligament, were by no means rare occurrences. According to our modern view of suppuration, we sought its source in a purulent salpingitis. If the fimbriated extremity allowed the escape of a drop of pus, we comprehended the subsequent localized peritonitis, the purpose of which was to shut off the focus of suppuration from the rest of the pelvic or abdominal cavity by plastic or formative inflammation around the focus. Since we knew that the presence of the staphylococcus, or rather its ptomaine, was a requirement to produce suppuration, we

considered this process an infectious one, the micro-organism being carried from without to the endometrium, from there into the tubes, and thence into the peritoneal cavity. The process known by the term of suppurative oophoritis, leading to a partial or total destruction of one or both ovaries, was not quite so common. Obviously this process in most instances arose from the contact of the ovary with a focus of suppuration in its immediate vicinity, the broad ligament. In cases where the ovary was only partially destroyed we found it, after extirpation or at post-mortem examination, bordering on an abscess cavity, and changed to such an extent that it was often not recognizable to the naked eye. Often there was no difference in the appearance or consistence of the remnants of the ovary. Under these conditions the microscope would have to be brought to bear to ascertain how much of the ovarian tissue was left. The author had come into possession by operation of a number of specimens of suppuration of the ovaries, and of these he had made a thorough microscopical study. According to the different tissues involved, the pathological conditions were described under the following headings: Fibrous connective tissue; inflammatory infiltration of connective and smooth muscle tissue; myxomatous tissue; changes in epithelial tissue. He gave a description of the inflammatory changes of all constituents of the ovaries. To the author's knowledge such had never been previously described, and he thought they would prove of great value in proving that inflammation and suppuration in the ovary were not always based on an immigration of colorless blood-corpuscles, as had been asserted some twenty years ago by Cohnheim. It was the author's conviction, from a very thorough study of the subject, that all constituent tissues of the ovaries participated in an active manner in the production of inflammatory corpuscles, which, being broken asunder, furnished that which we knew by the name of pus-corpuscles. The author gave a description of a number of his cases. They were selected from those that had not derived their source from a uterus containing any septic tissue. In many instances a positive diagnosis could not be made, but constant pain not associated with the menstrual period was suggestive of some ovarian trouble. Where abscess was diagnosed the abdomen should be opened in every instance, as patients in such a condition were in constant danger. If rupture took place into the peritoneal cavity, and the streptococcus and staphylococcus were present, the peritonitis was always rapidly fatal. It was rare for ovarian abscesses to be larger than a hen's egg; in the cases reported where they were of large size the chances were that they were some other condition. The author thought that these cases of ovarian abscess occurred more frequently than was supposed, but that they were confounded with other pathological conditions. Chronic suppurative oophoritis existed where no micro-organisms were present. This should not, however, deter one from operation, as innocuous pus could readily become noxious.

Dr. EDEBOHLS thought with the author of the paper that the ovarian tissue was capable of breaking down into pus cells. One of the factors in the causation of ovarian abscess not mentioned by Dr. Boldt was the gonococcus. These micro-organisms had been demonstrated in ovarian abscess where there was no break in the ovarian tissue. In regard to diagnosing these small abscesses, it was the speaker's practice to pass an exploring needle through the abdominal wall into the tumor and demonstrate the character of its contents. Pus had been frequently found in small tumors where the size and symptoms had not called for operation, but the demonstration of pus had. The frequency of ovarian abscesses varied in different countries. The Germans reported a very inconsiderable number, while in this country the proportion was very large. Out

of thirty cases of operation for diseased ovaries containing muco-pus, etc., fourteen were purely cases of ovarian abscess. The rational therapeutic measure in this class of cases was extirpation. He first emptied thoroughly and then enucleated.

Dr. COE was glad that Dr. Boldt had made a distinction between tubo-ovarian and true ovarian abscess. He was also satisfied that gonococci were a frequent cause, as well as that contamination could take place from the bowels, which cause operated through the lymphatics. One of the very serious complications of pregnancy was an unsuspected ovarian abscess. These ovarian abscesses were usually small, and situated high up, and it was hard to distinguish appendicitis from such. In one case where the author had operated for appendicitis in McBurney's line he had found an ovarian abscess, and in another case where the operation was done for supposed abscess of the ovary appendicitis was found.

Dr. A. H. BUCKMASTER thought that the *Bacterium commune coli* was a more frequent cause of ovarian abscess than was supposed. He did not think it impossible for it to penetrate the wall of the ovary, which was in close connection.

Dr. JARMAN referred to the very characteristic odor of these abscesses, and wondered whether there was any connection between them and the intestinal canal. In one case where he was operating he had been almost sure that he had opened the intestinal canal, from the very foetid odor which came from the parts, but he found that it had come from the ovary.

Dr. HANKS thought that the odor was not surprising, as all old abscesses where the pus had remained encapsulated for a long time had an intolerable odor. It was his practice to aspirate and enucleate in these cases as soon as possible after a diagnosis.

The CHAIRMAN agreed with Dr. Coe that the vagina was not the proper canal for drainage, for the reason that the true ovarian abscess was small and contained only about a drachm of pus, and was also adherent high up.

## New Inventions, etc.

### AN INSTRUMENT FOR THE DETERMINATION OF HETEROPHORIA.

By GEORGE T. STEVENS, M. D.

In the determination of the various tendencies of the ocular muscles, it is often advisable, and even necessary, to bring to our aid as many forms of evidence as can be made subservient to our purpose.

While the phorometer remains pre-eminently the reliable and efficient working instrument in the determination of heterophoria, auxiliary means are often required to confirm or to explain its indications. We sometimes also require an instrument for making provisional examinations, more portable than the phorometer.

As such an auxiliary and provisional instrument I have devised the stenopaic lens, which possesses manifest advantages (Fig. 1, A).

The purpose is to present contrasting images to the two eyes.

With the lens, the image of a candle-flame twenty feet distant, seen through the stenopaic opening, is a large and perfectly defined disc of diffused light.

If, for the purpose of effecting a diffusion, we employ the uncovered convex lens, a very slight movement of the lens, in or out, up or down, gives to it the effect of a prism in those various directions.

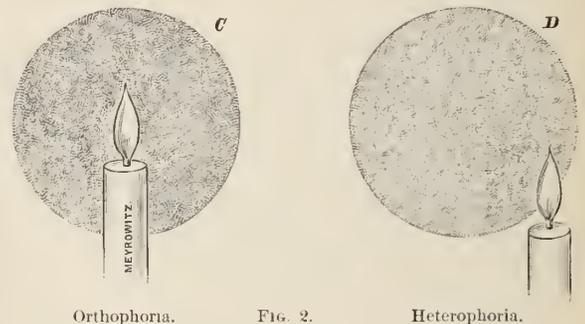

If a convex lens, about 13 D., is covered, except at the optical center, where a circular opening of three millimetres or less diameter acts as a stenopaic window, the small opening serves the double purpose of preventing an adjustment of the lens as a prism and of cutting off the halo in such a manner as to give the impression of an

exact disc of light bordered by a frame. A metal or hard-rubber disc of the size of the lens of the trial-case, perforated by an opening of the required diameter and supplied with a perfectly centered lens, is a convenient form. It may be used with a handle (Fig. 1, B), enabling the patient to hold it in his own hand, or it can be placed in the trial-frame.

In orthophoria the untransformed image should be found exactly in the center of the disc. In heterophoria it will tend toward or beyond the border. If the flame sinks below or rises above the center, while at the same time it deviates laterally, we thereby discover by a single comprehensive view all the elements of a compound deviating tendency, so far, at least, as that tendency is manifest (Fig. 2). In this important respect the stenopaic lens presents a feature both unique and of much significance. While by other methods of inducing diplopia or contrast we may discover, at a distance of some metres, first one and then the other element of a deviating tendency, by this instrument all the collective elements are presented simultaneously to the eye, thus eliminating a very important source of error.

FIG. 1.

Orthophoria.

FIG. 2.

Heterophoria.

In respect that it is simple, cheap, and small enough to be carried in the vest pocket, and that it, more than any of its class, represents the true relation of the visual lines, it is a useful test. Its disadvantages are those common to every instrument held close to the eye when in use in these examinations. This instrument has been manufactured by E. B. Meyrowitz, 295 and 297 Fourth Avenue, New York.

### EDINGER'S DRAWING APPARATUS FOR LOW MAGNIFICATION.\*

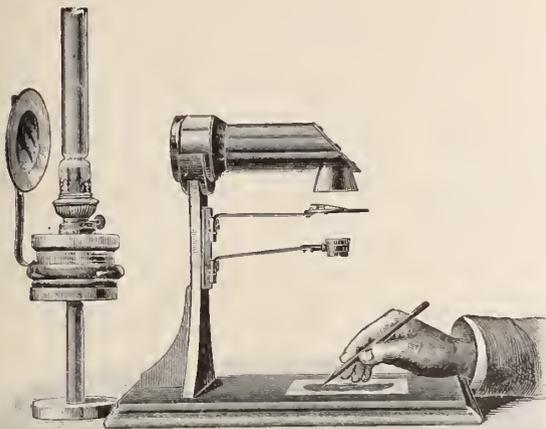

By JOSEPH COLLINS, M. D.

With the permission of Dr. Ludwig Edinger, of Frankfort-on-the-Main, I am permitted to demonstrate to you this evening the drawing apparatus devised by him and presented at the Southwest German Society for Neurology and Psychiatry, June 7, 1891.

The apparatus is based on the projection principle and consists of a

\* Presented before the New York Neurological Society, October 4, 1891.

stand bearing an upright which supports a tube or cylinder parallel to the base and in apposition to a piece of canvas board which cuts off all the rays of light excepting those passing through the cylinder.

The front surface of the upright has a metal groove into which is fitted at its upper part an arm terminating at the other end in a circular plate for the support of the object to be drawn. Beneath this is a second arm, also fitted into the groove, terminating in a small cylinder for the reception of the lens. Both of these arms are movable, but the upper one should remain fixed, while moving the other focuses the rays of light and makes larger or smaller representations of the preparation according to its distance from the object bearer. The light used may be either sunlight or artificial. As a rule, an ordinary lamp, with or without a small reflector, answers all purposes. The light being placed in the proper position, and the preparation to be drawn on the object table, a sharply outlined picture of the preparation will be thrown on a piece of drawing-paper beneath. By regulating the height of the arm bearing the lens, or by changing the lens, any magnification between two and fifteen times can be made.

In this way the outlines of an absolutely true drawing can be made and the details filled in from the microscope, or a precise picture can be made from the apparatus alone, so sharply defined is the representation.

Of course, specimens colored with dark stains give more clearly differentiated pictures than the light ones.

The instrument is made by Meyrowitz, of this city, at my request, and may be had with two or three lenses. Two are all that are necessary ordinarily, but the third is important sometimes when the object to be drawn is very small.

## Miscellany.

**Influenza from a Veterinary Point of View.**—The following paper, by Mathew Wilson, M. R. C. V. S., of Wenona, Ill., appears in the January number of the *Journal of Comparative Medicine and Veterinary Archives*:

Influenza is a disease that has long been known to medical science, both human and veterinary. Its history can be traced back with certainty only to the beginning of the sixteenth century, although as far back as the year 1300 we have accounts of an epidemic among the horses of Italy that seems to-day to be recognized as influenza. With the beginning of the sixteenth century we have accounts of epidemics, the wide distribution of which have been reached by no other acute infectious disease.

Up to the present time a great number of epidemics have been described, which generally extended over whole countries and frequently over several quarters of the globe.

They returned at indefinite periods and affected every season and latitude, advancing, as a rule, in a great wave.

In some cases they appeared to be preceded by sporadic cases, but more commonly a large number of the animals would be affected simultaneously, the disease spreading with great rapidity.

Among the numerous outbreaks, the following are recorded:

In 1648 an epizootic of this disease appeared in Germany, and from there rapidly spread to other parts of Europe, and in 1711 it attacked the horses of the European armies, causing great losses.

In 1732 the disease appeared in London, and later on in the same century in Scotland.

In 1766 we have the first attack on the horses of America, but not making its appearance here in anything like a virulent form until we have the extensive outbreaks of 1870-'72, when it spread over the entire country.

It is to-day an almost permanent disease among the horses of our large cities, where bad ventilation and want of sanitary arrangements about the great majority of stables seem to keep the disease alive, and perhaps predispose fresh animals to it.

*Definition.*—Influenza is a specific febrile disease, dependent upon a specific blood poison and prevailing as an epizootic.

It is essentially characterized by a catarrh of the respiratory and generally also of the digestive organs, by great and rapidly developed weakness, pains in the head and limbs, as well as by serious nervous symptoms and fever of greater or less intensity.

It is confounded generally with simple catarrh, but is distinguished by its wide diffusion, its rapid spread, and the number of cases in the regions in which it occurs.

We can not lay its cause to atmospheric influences, as we have it occurring at all times of the year, during different climatic changes and in countries whose atmospheric surroundings are totally different.

We have it occurring at seasons of the year when climatic changes are such as do not produce catarrh, and aside from this we have those lesions of function peculiar to influenza that can in no way be connected with a simple catarrh.

*Etiology.*—When we think of the numerous opportunities presented by this disease for investigation, and to what extent literature has been published upon it, we are surprised at what few facts have been gathered together concerning its cause and origin.

A great many theories have been advanced as to the aetiology of influenza, such as that of atmospheric influence; others give it a specific origin, but have never been able to isolate and demonstrate its specific cause, while on the other hand there are those who claim it has a spontaneity of origin, due to want of sanitation. This last is, I think, the weakest of all, as we have it occurring where sanitary arrangements are the best, as well as where they are almost entirely wanting.

The theory of its specific origin is, I think, conceded by the majority to be the correct one, although we have as yet been unable to produce conclusive evidence.

It is due to a *living miasm*, capable of being carried onward by the air, but having an independent existence of its own, and which would find in certain places conditions more favorable for its development than in others.

Take, for example, the last outbreaks of influenza in the human family, which seemed to have been developed in Russia and spread in the direction of human intercourse and the prevailing winds from the east to the west.

This living miasm is capable of transmission through the air, of being carried by human beings, or, in fact, by any of the known modes of infection.

Influenza has been described as the sum of a series of catarrhal manifestations, which have developed under common epidemic influences, and the intimate association of the various local affections allows us to give them a common specific origin.

Many acute local affections, such as acute catarrh, laryngitis, etc., present very much the same symptoms locally as in this disease, but there is wanting the sudden and general seizure, the severe nervous depression, and the extent to which the mucous membranes are involved; all these seem in favor of a general cause which has a specific effect upon the whole body.

These symptoms are much more severe than in the local affections, while they remind us more of analogous symptoms in other acute infectious diseases, and for these reasons I think we are justified in classing it under the same group.

There is a close analogy between the first symptoms of influenza and measles in the human subject.

Before the eruption occurs on the skin in measles there is found to be a catarrhal affection of the mucous membranes lining the air-passages, and also of the conjunctiva. This catarrh is so constant a manifestation that it has been considered a pathognomonic symptom, especially in those cases where the eruption can not be seen. Here it is, as in influenza, one of the earliest and most constant symptoms.

In canine distemper we have another disease whose early symptoms coincide with those of influenza.

Here we have the disease ushered in with chills, a dry, irritated condition of the mucous membranes, where the discharge soon becomes more copious, great debility, and in some cases an extension of the inflammation along the respiratory tract to the lungs and pleura.

In these diseases we have two that are recognized as being due to a specific organism, presenting characteristic symptoms that almost coincide with those of influenza; and what more probable to assume from this, that in influenza we also have a disease whose ravages are due to a similar cause?

*Pathology.*—The pathological changes in the body are due to the absorption of the morbid material by the blood. The alteration occurs in the blood, where we have a rapid destruction of the red corpuscles. The absorption by the tissues of these disintegrated corpuscles gives them a yellowish tint and a congested appearance. The first sign of this is seen in the early discoloration of the mucous membranes.

Along with this we always have more or less congestion of the various organs of the body.

Other pathological changes are due to complications; as, if the lungs are affected, we have the changes due to pneumonia or pleurisy. If enteritis or congestion of the liver is the complication, we have the changes taking place in them.

*Symptoms.*—The development of the symptoms of this disease, after a period of incubation varying from four to eight days, may result in a very mild attack, or they may be very intense.

In a mild attack we have the disease running its course as a specific fever, with only the alterations in the blood; but if the attack is severe, we may have it complicated with inflammatory diseases of the various organs, aggravated by the already weakened state of the body and the alterations in the blood, which have a tendency to favor a fatal termination of these complications.

The first symptoms are those of great indisposition, rapidly developing fever, which may become intense, chills of the body, staring coat, loss of appetite, and a dry, irritated condition of the mucous membrane.

The pulse becomes increased in number, varying from 60 to 80 and even 100; it may be at first moderate in volume, but becomes weak.

The discharge from the mucous membranes at first is thin and acrid, but as the disease advances it becomes more copious and thicker.

In the condition that is known as pink-eye we have the discolored pink condition of the mucous membrane lining the nasal and buccal cavities and the eyelids, tumefaction of the limbs and eyelids, great stupor, and the animal very weak.

The fever may run up as high as 105° F. or 106° F., and generally lasts from three to four days.

At the end of this time, if the disease runs a favorable course, the fever begins to abate, the appetite returns, the various organs take on their natural function, the pulse falls in number and becomes stronger, and we have the animal left convalescent in a weakened condition.

Death in these cases may be the result of an excessive fever, with failure of the heart's action, asphyxia from a rapid congestion of the lungs, or from the poisonous effect of the morbid matter due to disintegration of the blood-corpuscles.

*Complications.*—The complications, as we have before mentioned,

are generally of an inflammatory nature. As a result of the primary lesion, we have a congestion of the various tissues.

This, along with a distended state of the blood-vessels, a weak heart's action, and an improper aeration of the blood, is very prone to be followed by an inflammation, due to the slightest irritating cause.

During some outbreaks we have the majority of cases complicated with an inflammatory condition of the lungs; in others we have the complications arising in the bowels or liver. Why this should be we can not determine, unless it is that local climatic changes or atmospheric influences may be the exciting cause of these local lesions, the animal becoming more predisposed, due to the pre-existing disease.

To enumerate the symptoms of the various complications would be to go into those of pneumonia, pleurisy, enteritis, etc., which I do not think would throw any light upon our subject, and which could only be thoroughly discussed under their respective heads.

*Treatment.*—Treatment must, of course, depend upon the symptoms exhibited by each particular case; but there are some measures that will equally apply to all.

Great care must be taken to keep the animal free from exposure to draughts, and at the same time have ventilation sufficient to provide him with plenty of fresh air.

He should be well covered with sufficient blankets to keep up external heat, the legs hand-rubbed and bandaged, and his surroundings kept clean.

Antipyretics are indicated from the first. Of these we have a great variety, and selection must depend upon the practitioner.

I have found a combination of digitalis and nitrate of potash a good remedy, giving it twice a day.

In this we have not only a febrifuge action, but we strengthen the heart, lower its pulsations, and have a diuretic effect.

If the fever remains high, two or three doses of acetanilide, combined with digitalis, sometimes have a good effect.

If the attack is mild, generally all that is needed is good nursing and salines dissolved in the drinking-water.

If there is a tendency to constipation, a powder of sulphur and nitrate of potash each day will generally relieve it, along with warm bran drinks or linseed tea.

The treatment in complications must, of course, depend upon the accompanying disease, remembering at the same time the weakened state of the animal, and let our treatment be such as will keep up our patient's strength.

**On the Use of the Newer Antipyretics in Influenza.**—Little progress seems to have been made, says the *University Medical Magazine*, in the treatment of this malady. This is but what would be expected, however, owing to the obscure nature of the aetiology and pathology of the disease. Although there is every indication that the affection is caused by a specific micro-organism, the particular one remains to be demonstrated.

As the manifestations of the epidemic influenza are not the same in different epidemics, or, in fact, in the same epidemic, and as at present we do not know of any specific, a large field for experimental therapeutics has been offered by the more or less constant prevalence of the disease during the past two years. This has not resulted in the discovery of any new remedies, but we have learned what *not* to use.

During the past few years the chemical laboratory has furnished us with many new drugs, an important series of which possess remarkable antipyretic properties, and, as ascertained later, some of them are analgesics as well. These qualities seemed to indicate particularly their use to combat the fever, as well as the local or general pains so frequently complained of in the present epidemic.

Disappointment, however, often followed this method of treatment, and some of the deaths which occurred in the early part of the epidemic are charged to the use of these drugs. Evidence has been accumulating that these new antipyretic drugs are capable of acting as cardiac depressants. This is, perhaps, particularly the case when the heart is already weakened from other causes. Bearing in mind the profound prostration in many cases of influenza, it will be apparent that the drugs in question are dangerous weapons.

It seems that any one of the various systems of the body—the re-

spiratory, the nervous, the vascular, or the digestive—may be particularly affected by the disease under consideration. This may be explained by the theory of a *locus minoris resistentiæ*. When the violence of the disease falls upon the circulatory system, it is very important to avoid all cardiac depressants. This becomes of even greater significance if the heart or vessels be already diseased. The same caution should be observed in the case of children and the aged, among whom the disease numbers the majority of its victims.

It is to be recommended, therefore, that in this disease the new chemical antipyretics be used very cautiously, or not at all. It must be remembered that during the prevalence of influenza all diseases are apt to have an increased mortality, so that the same caution is to be borne in mind. It is, perhaps, superfluous to remark that the same argument holds good in the cases of the other cardiac depressants.

**Some Mooted Points concerning the Vomiting of Pregnancy.**—At a meeting of the Philadelphia County Medical Society, held on December 23, 1891, Dr. T. Ridgway Barker read the following paper:

In discussing the ætiology, symptomatology, and prognosis of the digestive disturbance associated with gestation known as morning sickness, or the vomiting of pregnancy, it becomes necessary at the very outset of a comprehensive study of the subject to exclude those forms of gastric trouble which, while often accompanying this purely physiological process, are nevertheless not dependent upon it for their existence, but upon some pre-existing morbid condition which is simply aggravated by the changes incident to gestation.

From a failure to appreciate and differentiate between these forms of gastric disturbance is largely due the confusion and misconception which is so general, hence the existence of such a multitude of views as to the cause and gravity of the vomiting of pregnancy.

It becomes necessary, therefore, that we state clearly that when we speak of morning sickness we do not include the so-called vomiting *in* pregnancy, but confine our remarks solely to the vomiting of pregnancy. Without further explanatory remarks, let us proceed to a consideration of the subject from a scientific standpoint, ever mindful, however, how easy it is to advance a theory and how difficult to find evidence to support it. That the occurrence of vomiting without apparent cause in females who have exposed themselves to the risk of conception is a sign of much importance is generally admitted, since it so quickly follows cessation of menstruation, and therefore further tends to confirm the presumptive evidence of pregnancy. With reference to its ætiology, one finds as many views as there are stars in the sky, each differing from the other in magnitude and brilliancy even as these distant orbs of light. Let us then turn away from such a merry-go-round of medical opinion and seek to discover the truth in the realms of anatomy and physiology rather than in the domain of idle speculation.

Coincident with conception we find a general rise in the intrapelvic blood-pressure resulting in increased activity on the part of all the viscera therein contained which are concerned in the process of reproduction. Cells heretofore carrying on a passive existence now spring into a high state of activity. Likewise there occurs hyperplasia and hypertrophy of tissue which is especially rapid in the uterine muscular elements. Nerves, which in the unimpregnated condition possess but a low grade of sensibility, now become highly sensitive and transmit readily to their respective centers slight disturbances, which, under other circumstances, would fail to throw them into a state of activity. What relation, one may very properly ask, exists between the vomiting of pregnancy and this exaltation of the nervous system? A causal one, most assuredly!

Can one fail to realize that this is a symptom of pregnancy due to the change in the nervous equilibrium induced by the process of gestation? Surely not. Rather are the nausea and vomiting expressions of a reflex irritation having its origin at the end-organs of the uterine nerves, which, as we have seen, are in a hyperæsthetic state. As the growing ovum demands, day by day, an increased space for its development, these end-organs are subjected to a varying degree of irritation which is transmitted to the centers and thence reflected out along the nerve-filaments distributed to the stomach. Why this affection is of more frequent occurrence and of greater severity in the first than in

subsequent pregnancies one can readily understand by comparing the cavities of the primiparous and multiparous organs.

We find in the former that the uterine muscular walls are convex and nearly, if not quite, in apposition, hence the capacity of the organ in these females is relatively less. Not so the multiparous uterus, for its walls are concave, and the capacity is further increased in length by half an inch owing to incomplete involution on the part of Nature after the first pregnancy. Need we seek for more conclusive evidence than this to support our position? Is it not plain to be seen that the resistance in the primiparous organ will be greater and the nervous disturbance more pronounced than where the cavity is larger, thus allowing the ovum to undergo its development without interference? Further, the period when nausea and vomiting are most apt to occur is in the second month, at a time when the growth of the uterus is principally lateral and the villi of the chorion are thrusting themselves into the serotine or placental decidua. As to the character of its onset, it is usually gradual and disappears in a similar manner as the uterus rises out of the true pelvic cavity, thus having quite ceased by the end of the fourth month.

Concerning the symptomatology of this affection, it has not a few well-defined characteristics. The primary nausea and oppression experienced over the epigastrium soon gives place to vomiting, not, however, preceded or accompanied by any degree of nervous depression as is the case with emesis under all other circumstances. The food, if any is present in the stomach, is expelled, not violently or with any amount of retching, but almost as if it were regurgitated. Should the stomach be empty, then simply a little clear, normal gastric mucus is raised, which, as it usually occurs early in the morning, has given rise to the popular appellation of morning sickness. Further, if the matter vomited be food, it will not be found on examination to be sour or to have undergone decomposition, but in a more or less perfectly digested state, depending upon the length of time since its ingestion. As to the subsequent amount of nervous depression, in most instances it is practically *nil*, even when the vomiting is frequent and of long duration. This fact is very noticeable in some cases; the pregnant female may have just finished a hearty meal—for impairment of the appetite is rather the exception than the rule—when almost immediately afterward she will be obliged to evacuate the stomach, only to turn to the piano and find consolation for her lost breakfast. Rarely does one meet with a case of vomiting of pregnancy where the female's health has materially suffered, and this is what one would reasonably expect from a study of the symptomatology of the affection.

That this digestive disturbance is a purely sympathetic one is proved by the fact that by a strong effort of the will the female can not infrequently ward off an attack.

Should she, for instance, have accepted an invitation out to dine during this period of gestation, she can control the nervous irritability by a firm determination not to betray her condition to the assembled guests. It has been repeatedly asked, How can a woman suffer from morning sickness at one period of gestation and not at another? In other words, How is it that the attacks vary in severity in different pregnancies? Moreover, Why is it that one pregnant woman has morning sickness and another does not? Can this be explained on the hypothesis of reflex nervous irritability? Most assuredly.

The variability in the duration and severity of the affection is due to two factors: Greater or less irritation, and greater or less irritability. The question may here be asked, Is vomiting of pregnancy a physiological or a pathological process?

It has been stated that among women of a strong, robust type, vomiting of pregnancy is exceptional rather than the rule, as is the case in Europe and America. But this fact has no direct bearing on the case; it goes without saying that the stronger and less sensitive the nervous system, the less general and severe will be the sympathetic disturbance. One certainly is not warranted in stating that the vomiting of pregnancy is a pathological process, for it is due to a purely physiological cause. There exists no morbid alteration in structure or function of the nerves. The irritability is not pathological but physiological, depending upon the degree of sensibility of the nervous apparatus. Yet it has been claimed by some investigators that this very exaltation is evidence of some pathological lesion. Surely not. It

were, it seems to me, as reasonable to declare a person's brain diseased because he is irritated by Wagner's music, in which he finds no harmony, as to declare that the sympathetic disturbance excited by pregnancy is due to some morbid process.

Again, if we select two galvanometers, one registering the weakest electric current, the other equally well constructed but less sensitive, we can not say that the former is any more perfect than the latter; they differ simply in the degree of their sensibility. Difference in sensibility within certain prescribed limits is a physiological, not a pathological fact. While vomiting, as Austin Flint points out, is not, strictly speaking, a physiological process, yet under these circumstances it is far from pathological; rather let us say it is the pathological expression of a physiological process. The vomiting of pregnancy, unless complicated by some morbid process, never gives rise to alarming symptoms or threatens life. If prolonged beyond the period of quickening, its continuance may be accepted as positive evidence of some complication which a decided alteration in the character of the vomited matter will usually indicate.

Cases of pernicious vomiting call for diligent search for organic lesions in the nervous system or structural changes in some of the generative or associated organs. That the vomiting of pregnancy occurs in healthy, strong women almost as frequently as in their less robust sisters, though in a milder form and of shorter duration, only confirms the view as to its physiological nature. The view advanced, that the difficulties of parturition are proportionate to the severity and length of the morning sickness, one is scarcely prepared to accept. The gravity of the digestive disturbance is to be estimated by the amount of nervous irritability, while the difficulties attending parturition may be classified under two heads—maternal and fetal. The former including uterine inertia, pelvic deformity, and rigidity of the soft parts; the latter, abnormal size of the fœtus and malpositions of the fœtus. Surely no such conclusions are justified, for the reports from the large lying-in hospitals of both America and Europe unmistakably prove that no such relation exists. Females who have suffered great annoyance from morning sickness have frequently as easy and sometimes more rapid labors than those who have almost wholly escaped this unpleasant early indication of pregnancy. Therefore, in conclusion, it would appear, from a study of this affection: 1. That the vomiting of pregnancy is due to a reflex irritation produced by the developing ovum acting upon an exalted nervous system. 2. That it is not an affection of great gravity and need occasion no anxiety or alarm. 3. That active treatment is rarely demanded, as it is only a disturbance of a few weeks at the most. 4. That the severity of the gastric trouble is no indication of the character of the subsequent labor. 5. That where the affection persists beyond the period of quickening, it is due to pathological causes which must be discovered and treated accordingly.

**The late Dr. William H. Van Wyck.**—The following is from the minutes of a meeting of the medical board of Charity Hospital, held on January 2, 1892:

The medical board of Charity Hospital has heard with profound sorrow of the death of their colleague, Dr. William H. Van Wyck, which occurred on the 16th day of November, 1891.

Dr. Van Wyck was one of our oldest members, and was endeared to us all by his geniality and kindness of heart. He was an esteemed member by reason of his broad knowledge of medicine and of surgery, and of his rare talents in practical therapeutics.

The members of the board therefore hereby express their great grief at the removal of their esteemed colleague by death, and extend their sincere sympathy to the widow, relatives, and friends of the deceased, with the assurance that they will ever cherish his memory.

Committee. { ROBERT W. TAYLOR,  
HENRY GOLDTHWAITE,  
THOMAS H. BURCHARD.

**The Association of Military Surgeons of the National Guard of the United States.**—The second annual session will be held in St. Louis, on April 19, 20, and 21, 1892. An interesting programme of addresses by prominent surgeons of the National Guard and the United States Army has been arranged, papers on military and accidental surgery will be read and discussed, and all matters pertaining to the health, useful-

ness, and welfare of the civilian soldiers will receive attention. The afternoon of one day will be set apart for an object lesson from the *Manual of Drill* by hospital corps of the United States Army detailed for this purpose. The evenings will be given up to entertainments, receptions, and banquets, for which the medical profession and generous citizens of St. Louis have pledged \$10,000. It is very important for the committee to ascertain as early as possible who will attend this meeting, and they ask for the name, rank, and address of those intending to be present, how many will form the party, and what hotel accommodations are desired. The fatigue uniform will be worn during the day and full dress at all evening entertainments. Full dress is not compulsory. Those intending to read papers are asked to send the title to Colonel E. Chancellor, 515 Olive Street, St. Louis, by March 1st. Transportation will be satisfactorily reduced on all railroads and steamboats to and from this meeting, and all hotels have given a low and uniform rate. It is expected that not fewer than five hundred surgeons and assistant surgeons of the National Guard of the United States and their families will be in attendance, to all of whom the committee of arrangements extend a most cordial welcome. Lieutenant Ralph Chandler, 135 Grand Avenue, Milwaukee, is the corresponding secretary.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

Original Communications.

TARDY HEREDITARY SYPHILIS OF THE BONES.\*

By G. G. DAVIS, M. D., M. R. C. S. Eng.,  
 PHILADELPHIA,  
 SURGEON TO ST. JOSEPH'S HOSPITAL;  
 ASSISTANT SURGEON TO THE ORTHOPÆDIC HOSPITAL.

FOUR cases of this not very common affection have recently come under my notice. As its true nature is quite likely to pass unrecognized and mistakes in treatment made, and as these cases happen to be so typical, I have thought them of sufficient interest to be presented to the consideration of the fellows of the college:

CASE 1 is that of R. B. D., a boy aged fifteen years. He presented himself at the Orthopædic Hospital with an enlargement of the left tibia, accompanied by considerable pain. His history is as follows: He is one of a family of fourteen children, nine of whom died in infancy. One of these nine died of hydrocephalus; the causes of death of the others are unknown. One of the five children left—a girl—lived to the age of eleven years, and had a similar affection of the legs as is presented by this patient. She was also at one time deaf and blind, but these troubles improved under treatment. She is said to have died of membranous croup. The rest of the surviving children appear to be healthy.

The mother has had five miscarriages, and the father confesses to having had syphilis, but states that it was contracted after the birth of the other affected child. There is a history both of a primary sore and skin eruptions. About eight years

ago, and the pain still troubles him. He has been rubbing the leg with liniments, but has never been treated by a physician.

On examination, the left tibia is found much enlarged, particularly forward, and bent to a slight extent inward. The thickening begins above the ankle and extends to near the tuberosity. There is a superficial ulcer on the front of the leg half way up to the knee. The left extremity, as a whole, appears to be two inches longer than the right one. The inner side of the left tibia measures over two inches more than the right, and its anterior surface is two inches and a half longer than that of the tibia of the opposite leg. The fibula does not appear to be at all affected. This increased length of the left leg has caused the pelvis to be tilted, and produced a curvature of the lumbar spine with the convexity toward the right and a compensatory one in the dorsal region with the convexity toward the left. The left knee is bent inward in a genu-valgum position and the foot is markedly abducted, or in a state of valgus. Three years ago he was struck by a stone on the right leg

FIG. 2.

above the external malleolus. The injured part began to pain and swell, and the fibula of the right side is now enlarged for the space of six inches above the ankle joint. The enlargement, however, is not so marked as that of the tibia of the opposite leg. No other bones are affected, and the teeth are neither pegged nor notched, although somewhat uneven. The boy is

FIG. 1.

FIG. 3.

FIG. 4.

ago, when the patient was seven years of age, he was kicked on the left shin by a boy. The leg then began to swell and pain him, particularly at night. This swelling has gone on increas-

thin, illy nourished, and somewhat nervous. The deformity of the left leg of this patient is shown in Fig. 1.

A marked feature of the case was its high and irregular temperature, varying at times as much as five degrees in twelve hours. The boy was treated with syrup of the iodide of iron, and then bichloride of mercury and iodide of potassium. He

\* Read before the College of Physicians of Philadelphia, November 4, 1891.

improved at times, but eventually left the hospital not much better than when he entered.

CASE II.—William P., a boy aged thirteen years, was admitted into the hospital under Dr. Goodman's care. When eight years of age, during the summer time, he began to have pain in one of his wrists. He denied having injured the part, and there was no change in its external appearance. In a week's time he had pains all over him. These pains continued all that fall and winter. They were present more or less all the time, but were worse from four o'clock in the afternoon on. He was also chilly and wanted to be near the fire. The affection was supposed to be rheumatism, but treatment for that condition gave no relief. In the following summer the pains ceased and both tibias began to enlarge. The ankles and knees at this time were also thought to be affected. The bones of the left forearm, too, began to get larger. Since then he has had pain off and on; it is worse before and after wet weather. He has never, at any time in his life, had any eruptions on his body or any trouble with his eyes or ears. His teeth are good, strong, and even.

His mother gave the following family history: She has had fourteen children, the patient being the seventh; of these, ten are living; the other children are all healthy. Of the four who are dead, one was killed by a gunshot wound at the age of three years, and another died of some disease of the stomach at the age of five. The remaining two died at the age of two and four days, respectively. The physician in attendance said that there was something wrong with their hearts. A year and a half ago the mother had a miscarriage at five months. She does not know of any cause for it, and it is the only one she has ever had. The father is a strong and hearty man. He has never had any eruption of the skin, and the only illness he has experienced

enlargement, as shown in Fig. 2; both legs were likewise enlarged, as seen in Fig. 3, of the left leg. The foot of this leg also showed some valgus. Before he entered the hospital he fell and hurt himself, and a purple spot showed itself above the right ankle. He remained in the hospital four or five weeks, and, after leaving, this spot broke down, and his physician, Dr. Miller, removed a large sequestrum, after which the limb was left as seen in Fig. 4. A year and a half later the swollen part

FIG. 7.

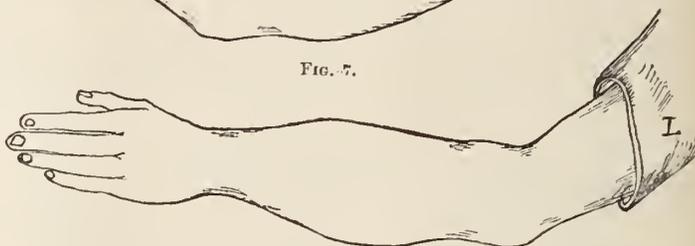

FIG. 8.

FIG. 5.

FIG. 6.

was six years ago, when he was very sick for four weeks. He was very hoarse, and the attack was thought to be bronchitis. The children did not suffer in infancy from snuffles or eruptions of any kind, nor from sore eyes.

On the admission of the patient into the Orthopædic Hospital both bones of the left forearm were the seat of a fusiform

below the knee of the right leg got quite red and painful and looked as if it was about to suppurate. While in the hospital this patient was treated with iodide of potassium and phenacetine and salicylate of soda at times for his fever. On leaving the hospital his acute symptoms had somewhat subsided, but otherwise he was about the same.

CASE III.—Willie S., a boy, aged eleven years, had been ailing for five years. He has had pains in his arms and legs, particularly the latter. These were thought to be rheumatic. He has been steadily getting worse, and now his legs are very much deformed, as are also his forearms. He has limped for the past two years. There is a valgoid condition of both feet, the left being the more marked. He complained while under treatment of a cold in the nose and throat. The cervical glands enlarged enormously, but after three or four weeks again subsided. Later on a large node appeared in the course of a single week on the left fibula just above the external malleolus, but immediately began to subside. The father admits having had gonorrhœa when young, but denies ever having had any symptoms of syphilis.

The mother states that there are two other children, now aged fourteen and sixteen years; they are and have been perfectly healthy. She has had three other children; two of these died of "water on the brain"—one at the age of three months and the other at seven weeks; the third was still-born. The head of this last child was also said to have been larger than was natural. She has had no miscarriages. Her husband has never had any trouble excepting rheumatism, from which he is getting better. The patient has a lupoid scar under the right eye, said to be from an abscess, and another on the side of the head measuring three quarters by an inch and a half. His legs increased gradually in size until they presented the appearance shown in Figs. 5 and 6. His forearms are shown in Figs. 7 and 8. The legs are the only parts that now pain him. He was never affected with snuffles in infancy, nor had he any eruption.

This patient was placed on the use of syrup of iodide of iron, twenty drops three times a day, and later was given iodide of potassium, five grains, and bichloride of mercury, one thirty-second of a grain after meals, and compound syrup of the hypophosphites, U. S. P., before meals. Improvement has been

marked and satisfactory. The arms have been reduced nearly to their normal size, and the size of the legs has also decreased. Febrile disturbances have never been marked in his case. Lately, however, a new node made its appearance on his left fibula, as already described, but has decreased much in size.

CASE IV.—William W., a boy aged thirteen. He was well until four years ago, when he was under treatment at one of our hospitals for disease of the right ankle. (See Figs. 9 and 10.) One year later the left began to swell (see Fig. 11), pain was severe, and he walked with great difficulty; at times he could not walk at all. He has also had pains in the left knee and hip, both in winter and summer. There is one scar on the outer side of the left tibia and two on its inner posterior surface. These were discharging eight months ago. The inner side of the right tibia is three eighths of an inch longer than that of the left tibia, causing the foot to assume a position of extreme valgus. (See Fig. 9.) His mother has had eight children, our patient being the fourth. Six are living, one died of scarlet fever, and one was still-born. No syphilitic history could be traced in either parent. The patient was placed on the use of iodide of potassium, and in about six weeks the left tibia was reduced to its normal size, and all pain in it

FIG. 9.

Later on one thirty-second of a grain of bichloride of mercury was given in addition to the iodide of potassium.

These cases are well-marked examples of an hereditary syphilitic taint which is tardy in its manifestations. The affection is to be distinguished from ordinary inherited syphilis because in it the manifestations of the disease occur usually during the first three months after birth, while

FIG. 11.

ceased. The right tibia, however, soon after suppurated and discharged three or four minute granules of bone, and still later an ulcer appeared on the right heel, near the tendo Achillis.

in tardy hereditary syphilis the symptoms may show themselves in childhood, youth, or even early adult age. In these cases the signs first showed themselves at the ages of seven, eight, six, and nine years, respectively. Fournier (*Syphilis héréditaire tardive*) describes one case, that of a young man who was attacked at the age of twenty-six years. Of course tardy hereditary syphilis can manifest itself by affecting other tissues than the bones, but they are the second most frequently affected. Eye troubles are the most common, embracing nearly half of all the cases, while the bones, according to Fournier, are affected in thirty-eight per cent.

The tibia is the bone most commonly attacked, and was affected in all the four cases here given.

In cases in which a syphilitic taint is suspected we naturally turn to the previous history of the patient if he is an adult, and to that of the parents if a child. The tardy or late manifestations of syphilis appear to be the last evidences that can be definitely attributed to the syphilitic infection. When it is attempted to attribute such lesions as are commonly regarded as serofulous or rachitic as being the result of a hereditary syphilitic taint, then we simply wander about in a speculative region about which nothing definite is known. It is, I think, a recognized fact that, as the duration of a disease is extended, so does the efficacy of purely specific remedies diminish, and certain it is that purely antisiphilitic treatment has not demonstrated its value in serofulous or rachitic affections.

FIG. 10.

While the peculiarity of the manifestations of the disease in the patient may establish the diagnosis positively, it still often occurs that a typical syphilitic history can not be traced in the parents. This is only to be expected, because we should remember that we are dealing with the manifestations of a disease that is on the point of losing its specific characteristics, and therefore does not exist in a virulent form. As the disease varies in intensity in different individuals, so we are apt to find the history to be a more or less typical one. In some, the more we search, the more numerous do we find the evidences of the syphilitic taint, and in nearly all some corroborative facts can be discovered. In the first case we find nine out of fourteen children dying in infancy; in the second, two out of fourteen; in the third, three out of six; and in the fourth, only one out of eight. A large infant mortality is characteristic of syphilitic parents, and in the first case this is markedly shown, but not so in the others, although three out of six in the third case is certainly suspicious.

Examining into the causes of death of these eleven infants, we find that, of the first five, one died of hydrocephalus, while the causes of the death of the other four are unknown. Of the second case, we find that the attending physician said the two infants died of heart trouble; they lived to the ages of two and four days, respectively. Of the three children of the third case, two died of water on the brain, and the third was still-born. Of the last case, the one that was lost was still-born. Haase (*Allg. med. Annal.*, February, 1829) and Lanceraux (*Syd. Soc. Transl.*, vol. ii, p. 162) state that hydrocephalus is occasionally associated with hereditary syphilis, and here we find three out of eleven children dying of it, and even one of the still-born children had a head larger than normal. It suggests the possibility of some of the cases of hydrocephalus which live much longer than these did as being due to a similar specific poison, although perhaps in a more attenuated and less virulent form.

Miscarriages are also symptomatic of the affection. We find that the mother of the first patient had five; of the second, one; and each of the other two had one child still-born. A clear syphilitic history of primary sore and skin eruption was obtained from the father of the first patient; but he claims they appeared after the birth of a sister of our patient, who was similarly affected, but he is probably mistaken. There was no syphilitic history on the mother's side. In the second case there was no specific history on either side, the father's only ailment having been an attack of what was supposed to be bronchitis, which disabled him for four weeks. It is possible that this may have been a specific sore throat. The parents of the third child deny all specific symptoms, the father admitting only that he had had while young an attack of gonorrhœa. No evidences of a syphilitic history could be obtained from the parents of the fourth child. The occurrence of osseous lesions such as are present in these cases has so frequently been observed in connection with other manifestations of the disease, and in cases in which the whole chain of evidence is complete, that there can not be the slightest doubt as to their cause. Such cases are given by Fournier, Hutchinson,

and others, and that of the first patient here presented is also one of that character. I have lately had referred to me a young married woman, aged twenty-seven, who, at the age of ten years, had an undoubted syphilitic ulceration of the throat, the soft palate being destroyed. This was followed later by syphilitic disease of the eyes, and from the age of twelve she has had trouble with one of her shins. It is tender and roughened even yet, and has probably been the seat of a syphilitic node.

The pain which exists in these cases is an important symptom. It begins when the patient goes to bed, and is less or altogether absent when he is up and about. It is said to be caused by the warmth of the bed-clothes, and that if the patient sleeps in the daytime he will have the pains at that time, instead of during the night. In Case II the pains began to get worse from four o'clock in the afternoon. The pains usually precede the enlargement of the bones, and at this stage the disease is very apt to be considered as being rheumatic. This occurred in some of these cases. The disease may either affect the bones near the epiphyseal cartilage or else the shaft. When the neighborhood of the cartilage is affected, the growth of new though not healthy bone is rapid—in fact, so rapid as to produce very marked deformities. The tibia being often affected while the fibula remains healthy, causes the foot to be thrown into a position of valgus. This was markedly the case with the left foot of patient one, the left foot of patient two, the left foot of patient three, and particularly the right foot of patient four. Mr. Hutchinson (*Med. Times and Gazette*, March, 1879, p. 348) details the case of a girl, aged seventeen, who had an enlargement of the middle of the femur which caused lengthening of the member. This shows that the increase in the length of the limb in these cases is not due to an increased activity of growth solely at the region of the epiphyseal cartilage, but that it likewise takes place in the diaphysis. Spontaneous fracture of the bone occurred in this case.

It is natural to look for other evidences of syphilis in the patient, such as notching of the teeth, but one should not necessarily expect to find them. Of course, some cases occur in which there has been a variety of lesions. Thus, the sister of our first patient had had both ocular and aural affections in addition to the bony lesions; also, in the case I have already mentioned, there were lesions of the throat, nose, and eye, in addition to the trouble with the tibia, but this is not commonly the case, and we are not apt to find the teeth affected. None of these four cases showed it.

A valuable diagnostic point is the multiplicity of the lesions, these being often symmetrical. In the first case the tibia of one extremity and the fibula of another were affected; in the second, the ulna and radius of one arm and both tibiæ; in the third, both tibiæ and one fibula and the ulna and radius of each arm; and in the fourth case, both tibiæ.

The pathological processes occurring in the bones is usually chronic, but at times it presents exacerbations, with marked sthenic symptoms. Severe pains, tenderness on pressure, increase in size of the part, redness, œdema, high

fever, and even suppuration followed by necrosis—all may occur.

The first patient, a boy aged fifteen years, had all these symptoms, and his fever was both high and irregular, varying from two to five degrees on an average. The second patient also, a boy aged eleven years, had marked febrile disturbances, the daily variation being from two to four and four fifths degrees. The third and fourth cases pursued a more chronic course, with very little febrile disturbance.

The nodes appear sometimes to be started by an injury as occurred in the first case, but this is not a usual occurrence. The disease affects both the periosteum and the bone itself. The rapid appearance of some nodes, as seen in the one occurring on the fibula of the third patient, and those shown by the unevenness of the crest of the tibia in some of the others, demonstrates the fact that the periosteum is markedly enlarged together with the superficial layers of bone. The body of the bone itself is also often affected. This at first is the seat of a rarefying osteitis; the bone becomes softened, and may even, as in Mr. Hutchinson's case above mentioned, break spontaneously. The skin is not unfrequently discolored, and large blue veins can be seen wending their way beneath it. (See Figs. 5 and 6.) As the activity of the disease ceases, if the bony changes have not been too marked, much of the deformity may disappear. The forearms of the third boy mentioned have almost, if not quite, returned to their normal condition, and his legs likewise have much improved, but the bones of the forearm of the second case retain their deformed condition; the disease, however, was still at times active. Later on a condition of sclerosis of the bones may occur, and further change in their form will only be such as is due to their subsequent growth.

When suppuration occurs, it may either take place with considerable or little disturbance. If the first is the case, the swelling is apt to occur quickly, the skin becomes red, fluctuation occurs, and spontaneous opening takes place with not much discharge of pus; the bone quickly becomes bare and exfoliation of a superficial scale is apt to be rapid, although, if the bone is deeply involved, the necrosed piece may long remain attached at one of its extremities. If, on the other hand, the process is more chronic, a regular cold abscess forms with a scanty amount of pus, spontaneous perforation soon occurs, and small granules of bone are discharged, as in the fourth case mentioned, and healing soon takes place, leaving a scar. The process differs considerably in its course from that of tuberculous or strumous disease. In the latter, the course of the carious or necrotic disease is much slower and a larger, thicker mass of bone is involved, and the sequestrum comes more from the body of the bone. The sinus may also keep discharging for months, and even years, the disease remaining apparently *in statu quo*. In these syphilitic affections, however, the course, both in its onset and decline, is more abrupt. Of course, as mentioned above, exceptional cases do occur where, from the depth to which the bone is affected, separation of the sequestrum is much slower than is ordinarily the case. There is a difference also in the appearance of the two patients. The syphilitic ones are usually thin, pale,

ill-nourished subjects, while those with ordinary necrosis are often in quite good general health, and certainly have a much better appearance than that of the marasmic-looking subjects of hereditary syphilis.

In regard to the treatment of the affection, mercury and iodide of potassium are certainly the most useful medicines. The rapidity with which the bone troubles of acquired syphilis respond to the administration of iodide of potassium has caused it to be looked on with deserved favor, and, if one were to estimate its value in the hereditary form solely by that fact and what Fournier says of it, one would expect no trouble in the treatment of these affections after they had once been properly diagnosed. It remains true, nevertheless, that in many cases the readiness with which an affection responds to treatment is inversely proportional to the amount of time that has elapsed since its acquirement, and, as might be expected, these cases of tardy hereditary syphilis are not so readily curable as the affections caused by the acquired form are. Mr. Hutchinson recognized this when he said (*Illustr. of Clinical Surg.*, vol. i, 1875, p. 47) of the nodes of hereditary syphilis that they were not very definitely influenced by the iodide of potassium. The first two cases here detailed both received at some time antisyphilitic treatment, but I was unable to keep sufficient trace of them to definitely determine its value. The first patient was not much improved, while the second was, after a few weeks, bettered to the extent that his acute symptoms subsided, only to reappear later on. In the last two cases antisyphilitic treatment has been more continuous and more satisfactory; both patients have markedly improved, although neither is by any means cured. Mr. Hutchinson says that these nodes, after having lasted a while, may disappear spontaneously, and therefore one should not be too ready to attribute any favorable change that may occur to the action of our remedies. Antisyphilitic treatment certainly offers the best hopes of cure, and the physician should pursue it faithfully. Personally, I like to give the bichloride of mercury in tincture of chloride of iron with some syrup, and iodide of potassium in solution of the strength of a grain to the drop. Syrup of iodide of iron, syrup of the hypophosphites, and tonics may also be found of service in the intervals when it is desired to suspend the administration of the more specific drugs. I hardly think the treatment should be solely and continuously an antisyphilitic one, but rather combined with one suitable for strumous affections. Macnamara (*Diseases of the Bones and Joints*, p. 151) holds that, while the iodides tend to relieve the pains in the bones, they are not curative, and therefore he orders iodide of potassium and bichloride of mercury together in some syrup. He also advises surgical intervention at times. He states that a subcutaneous incision into a painful node is frequently attended with the greatest relief to the patient, and, when the pains in the bones persist in spite of treatment, he advises exposing them and making a linear incision with a Hey's saw. I did not have an opportunity of trying this in the first two cases, where it would almost certainly have been of service, and in the last two the symptoms improved under treatment to such an extent as to render it unnecessary.

## SOME MOOT POINTS IN ECTOPIC GESTATION.\*

BY X. O. WERDER, M. D.,  
PITTSBURGH, PA.

ON the 16th of May of this year there came under my care at Mercy Hospital, Mrs. R., aged thirty-eight years, married seventeen years, mother of five children, the youngest over four years of age. She also had four miscarriages, the last one two years ago. Her menses were somewhat irregular, sometimes appearing every three weeks, sometimes going over time, also more profuse and of longer duration than previous to the birth of her last child. She always had good health until three months ago, since which time she was subject to irregular pains referred to the lower part of her abdomen and over to the right iliac fossa, of a bearing-down nature, like labor pains. April 16th, just a month ago, she had a very severe attack of these pains accompanied with a feeling of faintness, so that she was compelled to go to bed. In two or three days she had improved sufficiently to be able to go about, but she had repetitions of these paroxysms at irregular intervals of a less severe character. During the last four weeks she was compelled to spend half of her time in bed, and was unable, when up, to attend to her ordinary household duties. For the last six weeks she has had a constant bloody discharge, never profuse, and at no time were there any shreds of decidua passed, as far as she was able to observe.

Mrs. R. is of medium height, well nourished, but rather pallid and anæmic. She complains of some pain in the lower part of her abdomen, extending over toward her right side, with bearing-down sensations. There is some tenderness on pressure over this region. Vaginal examination reveals a marked bilateral laceration of the cervix with erosions and cervicitis. Pushing my finger up toward the fornix vaginae, it encountered a mass filling up Douglas's pouch, causing the latter to bulge down somewhat, which I at first mistook for a retroflexed gravid uterus, but, on making a more careful bimanual examination, I discovered the fundus uteri pushed out of its median position over to the left side of the pelvis by this mass, which was very closely connected—in fact, almost continuous—with it on its right side, but the fundus was found projecting over it. The uterus was considerably enlarged and slightly movable; moving it also imparted some very slight motion to the tumor. The mass was situated in Douglas's *cul-de-sac* and extending over toward the right side, but was not attached to the right pelvic wall; in fact, my finger could easily be pushed up between it and the pelvis. It was soft, almost giving the sensation of fluctuation, at least at its upper surface, and seemed almost immovable; it was of the size of a large orange and slightly tender.

A positive diagnosis was not made. It seemed most probable that this tumor was either an ovarian cyst with firm adhesions to the posterior pelvic wall, or an intraligamentous or broad-ligament cyst. The possibility of extra-uterine pregnancy was also considered, the symptoms pointing to it being the menstrual discharge keeping up for six weeks and the paroxysms of pain.

Laparotomy was performed on May 23d. After pushing up the intestines and omentum, which covered the tumor and had formed loose and soft adhesions with it, dark blood appeared in the incision and my hand filled up with a soft, friable substance, which when brought to the surface was found to be semi-organized blood coagula. Several handfuls were emptied out and then the tube was brought up, which was dilated and ruptured and filled

with blood-clots and the, at least at one place, firmly adherent placenta. The fetus was not found. This blood tumor was situated principally in Douglas's *cul-de-sac* and partly also to the right of it, but did not fill up the whole right side of the pelvis. It was bounded in front by the right broad ligament and the uterus (which also formed the boundary line on the left side), above by intestines, and posteriorly by pelvic wall. There was no membrane surrounding it which presented the least resistance to the finger; after separating the intestines it broke right into the mass. The abdominal cavity itself, before the ruptured mass had been broken into, was entirely free from blood. Neither was there any sign of inflammation, the only abnormal condition being a marked congestion of the peritoneal lining of intestines and abdominal walls. The abdomen was washed out with distilled water, a drainage-tube inserted which was left forty-eight hours, and the abdominal wound closed. The patient made an ideal recovery and is now in excellent health.

This case is of great interest, because it proves to my mind the fact that not all cases of tubal pregnancy are fatal. Rupture in this case undoubtedly had occurred on April 16th, almost six weeks before operation; the hæmorrhage evidently was not very profuse, probably a slow oozing, because the symptoms at no time were of an alarming nature. The bloody serum in the abdominal cavity became absorbed, the coagula by the natural law of gravitation found their way to the lowest portion of the peritoneal cavity, the Douglas's pouch, when the protecting hand of Nature surrounded them by lymph, encysting them there and shutting this foreign body out from the general peritoneal cavity. That Nature's conservative efforts would have succeeded in restoring the patient's health in time is more than probable.

Simple as this matter seems, some of our best and experienced operators in this field doubt or even deny the possibility of this occurrence. Tait says that "intra-peritoneal ruptures seem to be almost uniformly fatal." "I have never seen a case of suspected rupture, or one in which we suspected intra-peritoneal effusion of blood, recover if left alone."\* Joseph Price, whose experience with ectopic gestation has been equaled only by Tait himself, seems to share this opinion. Their teaching seems to be that the only hope of recovery is in an operation. The only cases of tubal pregnancy which, according to Tait, recover spontaneously, are those rupturing between the folds of the broad ligaments, and such cases he regards apparently as quite common—so common that he has been able to see from fifty to eighty cases of this condition.

Price's experience differs from Tait's in this regard: in his opinion, rupture into the broad ligaments is extremely rare. He says: "Mr. Tait's position in regard to hæmorrhage into the broad ligaments differs from the rest of the world. I have operated fifty-four times for ectopic pregnancy, and I have failed to find hæmorrhage between the leaflets of the broad ligaments." †

The opinions of these two men should, by means of their unexcelled experience, be regarded as authoritative, but they disagree in a matter pathologically of great importance. There is no doubt that Tait's singular experience in regard

\* Read before the American Association of Obstetricians and Gynecologists, New York, September 18, 1891.

\* Tait on *Diseases of Women and Abdominal Surgery*.

† *Transactions of the Philadelphia Obstetrical Society*, February 5, 1891.

to intraligamentous rupture of tubal pregnancy has not been verified by other observers, nor can his statement in regard to the uniform fatality of intraperitoneal hæmorrhage be borne out by facts. I am of the opinion that many of these cases recover, and in this I am supported by Olshausen, Veit, and other authorities. My own experience, which, it is true, covers only six cases, has proved this to my own satisfaction. In addition to the case with which I introduced this paper, I have seen two other cases in consultation in which there could be no reasonable doubt about the existence of ectopic gestation with rupture into the peritoneal cavity, in which operation was refused and still the patients recovered. The first patient when seen by me was profoundly collapsed and exsanguinated and seemed to be on the verge of death. Both the attending physician, Dr. J. J. Buchanan, and myself urged laparotomy as the only hope of recovery, but this the patient refused. As this patient was very thin and the abdomen not tender, the examination was very easy. The fluid in the abdominal cavity could distinctly be made out. Bimanual examination discovered the uterus of but little more than normal size, movable, and pushed to the right by a boggy mass in the position of the left Fallopian tube. This mass was of about the size of a large orange, but somewhat more elongated. The sac of Douglas was filled with a doughy mass. The patient gradually rallied and improved, but very slowly, and her recovery was very tedious. Three months afterward I had an opportunity to examine her and found a mass in her pelvis of the size of a large lemon, and even then she was unable to attend to her household duties.\*

The history of the third case is almost identical with the one just narrated, with this exception, however, that her condition had never become extremely alarming and threatening as the other. She also recovered without operation; but though rupture occurred last April, her family physician, Dr. J. J. Buchanan, reported to me a few days ago that there was still a mass in her pelvis and that she was so very tender that examination could only be made with great difficulty. It is needless to say that though over five months have elapsed since her intraperitoneal hæmorrhage, she is still suffering from its effects.

Of the four cases in which I performed laparotomy, in one case reported in this paper the operation was made almost six weeks after rupture, when the patient was slowly recovering from an intraperitoneal hæmatocele; in two others rupture had occurred five days previous to operation; both patients were rallying from their condition of collapse and there were no signs of any renewal of hæmorrhage, and as the fetus in both cases had escaped from the tube into the abdominal cavity, it is at least probable that recovery would have taken place without operation. We have, therefore, five cases out of a total of six in which there is a strong probability of recovery, though undoubted rupture into the peritoneal cavity had occurred. Ordinarily we could hardly expect such favorable results, but I feel confident that the percentage of recovery is much larger than

we have been led to believe. Granted, then, that this be the case, should we change the method of treatment of this affection now generally advocated—namely, laparotomy as soon as this condition is recognized? I would say emphatically, No! There is too much uncertainty in this matter, and while undoubtedly many would recover without operation, there is a very large percentage which only prompt operation can save; unfortunately, we have no means of knowing which are the fortunate cases that would escape a fatal termination. Within a year I have had an opportunity to see two specimens of tubal pregnancy removed post mortem from cases unknown to me, which probably could have been saved by prompt operation. One of these, whose ovisac was not larger than a raspberry, died in a little over five hours. Promptness in operating should, therefore, be our rule; trusting in Nature to avert the fatal termination is illusory and is apt to be disappointing. I would advise, therefore, with Dr. Charles A. L. Reed,\* to operate—1. Before rupture as soon as the condition can be presumptively diagnosed. 2. In cases after rupture, as soon as evidences of internal hæmorrhage become apparent.

I think we all subscribe to this treatment, with the exception of those, perhaps, who still pin their faith to electricity. We are probably not so unanimous in the cases which have passed the most critical period, danger of death from hæmorrhage—*i. e.*, cases in which the hæmorrhage has ceased and the patients begin to rally and improve. Most authorities, I believe, counsel conservatism and advise against operation, but I doubt whether such a course would serve the best interests of our patients. On the one hand we have the danger of recurring hæmorrhage (cases in which bleeding returned at intervals of days and weeks have been reported by Veit, Olshausen, Price, Tait, and others) and an accumulation of blood in the abdominal cavity, which, in spite of the well-known digestive properties of the peritonæum, is liable to produce sepsis and peritonitis. Even if the hæmatocele has formed, there is still danger of sepsis and suppuration. If the patient survive all these dangers, her convalescence will be slow and tedious, as has been shown in the two cases referred to in this paper, and the tube which was the seat of the rupture will not only be a useless organ, but it may prove a source of ill health and possible danger to life at some future period. On the other hand, laparotomy should be, and has proved to be, a perfectly safe operation in skilled hands, especially in these cases, as they have already recovered from their collapsed condition; by it we are able to remove all present and future danger. In none of my abdominal work have I seen such ideal recoveries and such rapid convalescence as in the four cases in which I operated. The patients gained strength during the two weeks they spent in bed. One, in whom the pulse had been from 120 to 160 during the five days previous to operation, had a pulse of 90 the morning after operation. I would therefore, in the interest of the patient, advise laparotomy, though all present hæmorrhage had ceased and even if an intraperitoneal hæmatocele had

\* Reported in *Pittsburgh Medical Review*, 1891.

\* *Indications for Operation in Ectopic Pregnancy.*

formed, provided, of course, the operator has the necessary skill and the surroundings are favorable for an aseptic operation.

In closing this already too lengthy paper, permit me a few words in regard to a danger referred to by Olshausen,\* Reed,† and others, which patients with ectopic gestation are liable to encounter—namely, a recurrence of such an accident in the other tube. To avoid this danger it has been suggested to remove both tubes in operating for tubal pregnancy, justifying this course by the assumption that ectopic pregnancy is almost invariably due to salpingitis, which, in the large majority of cases, is bilateral. It is not my purpose at present to go into the ætiology of this affection, but to simply look at this matter in its practical bearings. Where the tube not the seat of fetation is seriously diseased, its removal is plainly indicated; but where no such marked disease is present, such a course, in my opinion, would hardly be rational. Of my four cases, in two the tube and ovary were perfectly normal; in one (the case reported in this paper), the left ovary was slightly adherent but the tube and ovary otherwise normal; in one only was the removal of the other tube indicated for disease. The result of this conservative course of treatment was pregnancy in two cases; one patient has been delivered of two living children since, and the other is in her seventh month of pregnancy.

## DISEASES OF THE URINARY APPARATUS.

BY JOHN W. S. GOULEY, M. D.,

SURGEON TO BELLEVUE HOSPITAL.

(Continued from page 70.)

### PART I.—PHLEGMATIC AFFECTIONS.

#### SECTION II.—SPECIAL CONSIDERATIONS.

##### IX.

#### TREATMENT OF THE ACUTE TYPES OF URETHRITIS.

URETHRITIS, liable to divers accidents, complications, and consequences, may be regarded as a stricture *in posse*, the germ of a stricture—in other words, urethritis and the consequent stricture may be considered as a continuous process whose evolution begins at the inception of the phlegmatic action and ends with the confirmed stricture. Therefore the general indications of treatment of urethritis are—1, to remedy the phlegmasia; 2, to guard against accidents and complications; 3, to prevent the formation of stricture; and 4, to minister promptly to other consequences of this phlegmasia. The special indications vary with the types, stages, and complications of the affection, with the peculiarities and general condition of the individual, and with his hygienic environment.

ABORTIVE TREATMENT.—The treatment of acute urethritis was for a long time based upon erroneous notions of its nature, and directed to the substitution, as it was believed, of a simple, inoffensive, for a specific phlegmasia.

\* *Extrauterinschwangerschaft mit besonderer Berücksichtigung der zweiten Hälfte der Schwangerschaft.*

† *Indications for Operation in Ectopic Pregnancy.*

This treatment, suggested in 1780 by Simmons, and afterward largely employed by Ricord, Diday, and others, consisted of urethral injections of nitrate-of-silver solution (ten, fifteen, or twenty grains to the ounce), and was named the abortive, to distinguish it from the methodical treatment. This supposed quick way was as delusive as it was alluring, alike to patients and to physicians, for it seldom cut short the attack of urethritis, and besides the great distress it caused, was often productive of grave effects upon the urethra and adjacent parts, the first effect being a super-acute urethritis, then peri-urethritis, lymphangitis, sometimes prostatitis, trachelocystitis, gonocystitis, orchitis, etc. Inasmuch as this too heroic treatment is still, though very rarely, recommended, it was thought necessary to give this note of warning to younger members of the profession against the employment of means which not only fail to remedy but serve to aggravate the affection.

Two other modes of abortive treatment were afterward employed: 1. The administration of balsamics alone. 2. The balsamics and urethral injections combined. They also have proved worse than useless. The balsamics alone were much used by Cullerier, who gave them in very large doses. He prescribed from twenty to fifty grammes of powdered cubebs each day, alternating with copaiba balsam, of which he gave from fifteen to twenty grammes a day in divided doses. Such doses may for a few days be tolerated by some stomachs, but how fatal they must prove to the faithful kidneys which distill the active principles of these drugs that, through the urine, they may act upon the diseased urethra!

The association of astringent injections with balsamics was extolled by Ricord when nitrate of silver failed. The substances used for these injections were sulphate of zinc and acetate of lead, or the two together, three and five grains to the ounce, repeated three times daily.

Urethral injections with copaiba-balsam emulsion have also been used, but soon abandoned on account of the great ensuing irritation. Then were vaunted many "infallible remedies," used by mouth or applied by injection or through soluble bougies, all of which have done infinite mischief. These panaceas were generally prescribed without regard to the particular stage of the phlegmasia.

A complete list of the drugs given for, and the modes of treatment of, urethritis that have been used and failed or caused serious harm would more than fill a large and thick quarto volume printed in small type.

METHODICAL TREATMENT.—To treat urethritis rationally and methodically, it is necessary first to ascertain the nature, cause, type, and precise stage of the phlegmatic attack, and the general condition of the sufferer.

*Hygienic Precautions.*—From the beginning to the end of this treatment the most rigid hygienic precautions should be taken, if only as prophylactic of accidents and consequences. Among the enjoinders are continency and avoidance of all manner of sexual excitation during the treatment and for a month after the cure, and abstinence from foodstuffs that may be trying to the digestive process or that are likely to act injuriously through the urine, which

is one of the most important factors both for ill and for good in urethritis. For ill, when it is excessively acid and charged with acid phosphates or with uric acid, or when it is excessively alkaline and loaded with triple phosphates. For good, when it can be kept bland and when it can be made the carrier of medicinal agents. Therefore the physician should keep a close watch over the urine throughout the treatment of urethritis. The diet should not otherwise be restricted, except in quantity, which may be a little less than in health, but not so decreased as to reduce the vital powers. An already feeble patient is benefited by a generous diet, with even a moderate allowance of wine, and is thus placed in a condition to recover from his urethritis much sooner than he would under insufficient alimentation.

The most scrupulous cleanliness should be observed. The glans penis should be bathed twice or thrice daily in a solution of mercuric chloride (one to ten thousand), and the patient cautioned against carrying his hand to the face or near the eye after touching the genitals, and to burn all cloths that may be impregnated with pus. The reason for these precautions should be fully explained to him, for they are among the most essential of the hygienic observances, without which virulent ophthalmia is almost certain to ensue.

The bed on which he sleeps should not be too soft, the covering should be as light as the state of the weather permits, and the room as little heated as possible. This, in a measure, tends to prevent erections.

Much walking or any prolonged exertion should be avoided, as either is conducive to complications and consequences, such as œdema of the prepuce, phimosis, lymphangitis, orchitis, etc.

*General Treatment.*—The first stage of urethritis or, as it is called, benign urethritis, which is the period of incubation of acute urethritis, should be treated with a view of favoring its early deliquescence. When a patient presents himself three or four days after a sexual debauch, complaining of a little ardor in urination, and has a slight clear mucous urethral discharge and some congestion of the mucous membrane at and within the meatus, the physician—after inquiring into the circumstances of the debauch, particularly if the culprits had both indulged freely in beer, wine, or spirit, and what was the degree of sexual erethism in both—is ready to pass judgment upon the question as to whether this is or is not the beginning of an acute urethritis. If he has a doubt, he should give the patient the benefit of that doubt by treating the case as if it were going to be acute urethritis. The treatment should first be directed toward rendering the urine as inoffensive as possible. If the urine contains a great excess of uric acid, four or five doses of ten grains each of sodium salicylate, largely diluted, should be given during the first day only. Afterward twenty grains of sodium bicarbonate, also largely diluted, should be given four times daily, adding the juice of half a fresh lemon to each dose, thus making a citrate of sodium, which is better tolerated by the stomach than the salicylate. The depletion produced by a brisk saline cathartic (an ounce of sulphate of sodium) is of much service in this stage of the

phlegmasia. Rest at this period is of much consequence, and may in the end be a great saving of time.

*The local treatment of the first stage of urethritis* consists of two daily irrigations of the phallic region of the canal with a solution of mercuric chloride (one to ten thousand, or even one to twenty thousand). The quantity for each irrigation should not be less than a pint of water at a temperature of 102° to 105° F. The greatest care should be taken against bruising or in any way irritating the urethra during these irrigations. A smooth, hollow bougie of gum or glass, not over four inches long, acorn-shaped at its vesical extremity, not larger than No. 10 English, with three or four perforations at the base of the acorn, may be used for the purpose. The bougie, fastened to the long India-rubber tube of a fountain syringe, is then gently passed into the phallic region of the urethra for about two inches and a half and the irrigation begun, the retrograde current washing all that part of the urethra anterior to the acorn, and running out into a vessel placed between the thighs of the patient, who should then be sitting upon the edge of his bed or chair. If the irrigations are well tolerated by the urethra, and if the urethral congestion is decreased in the course of two days, the treatment should be continued several more days to insure deliquescence of the phlegmasia. But if, on the contrary, the discharge increases and becomes opaque, showing the advent of the second stage, the irrigations should at once be stopped, as otherwise they would be likely to cause superacute urethritis and its consequences.

If, when a patient first applies for treatment, the discharge, instead of being clear mucus, is already opaque, it indicates the presence of pus and the beginning of the second stage. In such a case the local treatment by irrigations should not be employed. The first part of the treatment—*i. e.*, the citrate of sodium, etc.—should constitute the principal remedial means.

Patients very rarely apply for treatment until the second stage of urethritis is fully established. It is then that meddlesome treatment and polypharmacy are so often carried to the greatest excess, partly through the solicitation of the anxious patient, partly owing to misinterpretation of the phenomena of urethritis, and to the vain search for a specific, and it is then that the misguided employ blindly those heroic means which so surely lead to serious consequences.

*Subacute urethritis*, whose characters in its second stage are generally a free purulent discharge with little exfoliation of epithelium, comparatively little pain, very little scalding in urination, and no nocturnal erections, notwithstanding its mildness, is persistent and requires careful management lest it become acute or superacute. In the second stage of subacute urethritis the same hygienic precautions should be taken as in the other types, and the same diluent beverages as those used in the first stage, only it is wise to vary the drink every few days, substituting uva-ursi, buchu, or dog-grass tea for the citrate of sodium, and finally returning to the sodium citrate. In the subacute, like the other types, balsamics should not be used for several weeks, or not until the stage of decline, and should not be given in as large

doses; nor should irrigations be employed until very near the close of the period of decline, when the discharge has decreased to a few drops each day.

*The second or stage of increase*, of greatest activity, of the acute type of urethritis, during which it is steadily extending backward, attended as it is with much pain in urination, owing to extensive exfoliation of the urethral epithelium, and with painful nocturnal erections of the penis, demands an antiphlogistic medication. During this stage balsamics and injections are worse than useless, and provocative of complications and consequences which not only retard the cure but are in themselves of grave import. They should therefore under no circumstances be administered during that period. The amount of food should for a few days be lessened; a saline laxative, two drachms of sulphate of sodium in six ounces of hot water, should be given every morning; thirty grains of citrate of sodium four times daily for three or four days; a full bath of half an hour at a temperature of 102° during these four days, after which a nightly hot hip bath of five minutes is substituted; and absolute rest. Four or five times during the day the penis should be dipped, for cleansing and for urination, into a small vessel of warm mercuric chloride solution (one to five thousand). To combat the nocturnal erections of the penis, ten grains of camphor and one grain of hyoscyamus extract may be given at bed-time and once repeated during the night if necessary. For a fidgety algophobic patient a dose of thirty grains of sodium bromide largely diluted may be given instead of the camphor and hyoscyamus.

In this second stage superacute urethritis is similarly treated. To relieve the excessive pain during erection and chordee the penis should be immersed in a vessel of iced water, wherein the patient may then urinate much to his relief. A full dose of opium during the day and a rectal suppository of a grain of opium and half a grain of belladonna extract at night may be necessary to relieve pain and induce sleep. The application of ten or twelve leeches to the perinæum often has the effect of relieving extreme pain and of shortening the period of increase. This of course is advisable only in the case of strong and robust subjects.

*During the third stage*, or static period, this active antiphlogistic treatment is discontinued. The five-minute hot hip baths are, however, continued. The quantity of diluents is diminished or their constituents changed, and the case is otherwise treated in accordance with such new indications as may arise. The static period is generally of short duration, and if there be no complications or consequences, such as will be described later, the fourth stage soon begins.

*The fourth stage*, or period of decline, is ordinarily the beginning of resolution, which may be rapid and complete in two or three weeks, or slow and last four or five weeks, or incomplete and indefinite and merge into chronic urethritis. During this period of decline the phlegmasic phenomena are absent, and there is only the purulent discharge, which is less in quantity and very perceptibly altered in quality. It is no longer creamy and contains more mucus and less epithelium. There are no painful erections of the penis, and the urine has ceased to cause scalding pain. It

is at this time that the diluents should be suspended and that the balsamics may safely be administered, but not in the large doses so commonly given, such as three drachms daily of copaiba balsam or one ounce of cubeb powder. Both of these drugs, thus given, within three or four days become so nauseating that the most willing patients reject them. In moderate doses they are longer tolerated, but finally disturb the digestive process and have to be abandoned. About twenty-five years ago sandal-wood oil was suggested by Henderson as preferable to copaiba. Since then experience has demonstrated this superiority, and the sandal oil is now much more extensively used than copaiba, whose properties it possesses without its disadvantages. But even this oil should not be given in large doses. Two capsules, containing each ten minims of sandal-wood oil, may be taken four times daily for a week, then three times daily for another week, and during the third week the dose should be decreased until the patient shall have taken only one capsule, when the drug is discontinued. There are patients that can not bear even this comparatively mild treatment. Their troubles last longer, but after all get well without it.

*Not until the stage of decline is far advanced should urethral injections be used*, and then only if after the use of the balsamics there is still a slight discharge. Before this time even mild injections are liable to cause lymphangitis or peri-urethritis. Strong astringents should be particularly avoided. The ignorant believe that to cure a urethritis the urethral mucous membrane must be practically tanned. Injections, to be effective, should be used in large quantity, but in weak, unirritating solution, and only once daily during this stage of urethritis. The small urethral syringe containing an ounce of fluid, used three or four times daily, does more harm than good, for each introduction of its nozzle is a hurt to the urethra. Among the most efficient agents for urethral irrigation in these cases are the corrosive chloride of mercury (1 to 10,000) and the sulphate and chloride of zinc. Of a solution of sulphate of zinc, half a grain to a grain to the ounce of water, a pint is to be used at night or in the morning by means of the simple apparatus and fountain syringe already described, except that the hollow bougie should be about nine inches long in order that it may be carried as far as the sinus of the urethral bulb or farther if necessary, so that the whole urethra may be washed. The chloride of zinc, the other precious agent for urethral irrigation, should be used in even weaker solution than the sulphate—from a quarter to half a grain to the ounce. In some cases a solution of boric acid, two grains to the ounce, suffices to cleanse the urethra and arrest the discharge.

In the majority of cases this simple treatment, which can be applied by the patient himself, answers well, and the urethritis is cured in five or six weeks. Other cases, whether complicated or uncomplicated, are refractory to treatment and linger many months or years. These are principally cases of secondary urethritis, the patients having suffered from the phlegmasia once or twice before, or possibly being affected with granular urethritis or already with stricture, or perchance with urethral mucous patches

or tuberculosis. The special treatment required by these cases will appear in its appropriate place.

Among the medicinal agents that have been used in Bellevue Hospital for injections in urethritis may be mentioned solutions of the violet methylaniline, of permanganate of potassium, of permanganate of zinc, of phenol, of hydrastis, and many others, mostly with unsatisfactory results.

As a general rule, when uncomplicated urethritis is well cured there are no sequelæ. Some patients, however, suffer for many months after the cure from oversensitiveness of the urethra, unduly frequent urination, or a superabundant mucous secretion, due generally to hyperlithuria, and demanding a treatment appropriate to that condition. In other cases a very slight opalescent urethral discharge persists. In these cases the careful introduction of a bulbous bougie reveals one, two, or three tender spots along the urethra. These tender spots are places where there has been a greater degree of epithelial exfoliation than elsewhere in the canal, and the denuded spots, though afterward covered with granulation tissue, are oversensitive even to the passage of urine, and it is from them that issues the slight discharge. The treatment required is an occasional urethral irrigation and the introduction, twice a week for two or three months, of a steel sound to dilate the canal moderately, to restore its suppleness, to destroy the granulation tissue, to relieve the sensitiveness, and to prevent the formation of stricture.

*Conclusions.*—The study of the nature of urethritis and of the many modes of treatment proposed for its cure has led to the following conclusions:

1. There is no specific for urethritis, notwithstanding the popular belief in its existence.
2. Urethritis can not rationally be dealt with as a single phlegmasia entity, no matter what may be its cause.
3. The nature, course, and pathic properties of the different stages of the acute types of urethritis indicate that an exclusive method of treatment can not be carried out in all cases with a reasonable prospect of success.
4. The treatment that is suited to one type or stage of urethritis is often hurtful in another type or stage of the affection.
5. The same therapeutic agent, applicable to a particular type or stage of the phlegmasia, is not suitable to all individuals.
6. Balsamics are contra-indicated during the first three stages of urethritis, and should not be administered until the fourth or stage of decline is fully established.
7. Urethral injections are contra-indicated during the second and third stages of urethritis, but may be used in the first stage and toward the close of the fourth stage.
8. Injections of strong solutions of nitrate of silver, or of strong solutions of any kind, are contra-indicated in all the stages of urethritis.
9. Urethritis is ordinarily too much and too vigorously treated. The more heroic and meddlesome the treatment, the greater the liability to accidents and complications, and the longer the duration of the phlegmasia.
10. Confirmed acute contagious urethritis, under the

most favorable circumstances and the most judicious treatment, rarely gets well in less than four weeks, except of course in the first attack in young and otherwise healthy men who are not overtreated. In the last-named cases it sometimes gets well in ten days or two weeks without medicinal treatment.

11. Proper hygienic management is all-important in the treatment of urethritis; unless it is rigorously carried out, the medicinal and local treatments inevitably fail.

## OPTIC NEURITIS AS A FORM OF PERIPHERAL NEURITIS.\*

By ALVIN A. HUBBELL, M. D.,

BUFFALO, N. Y.,  
PROFESSOR OF OPHTHALMOLOGY AND OTOLGY  
IN THE MEDICAL DEPARTMENT OF NIAGARA UNIVERSITY.

PERIPHERAL neuritis, both clinically and pathologically, has assumed a recognized position in medicine to-day.

The attention of physicians in the past has frequently been directed to manifold sensory, motor, and trophic affections, but until recently the conjectured lesion has been located in the spinal cord or brain, or the disease has been regarded as merely functional. It was in 1866 that Duménil † first established by autopsy and microscopical examination the existence of extensive disease in the peripheral nerves as the cause of such manifestations, although Graves, of Dublin, had, nearly twenty years before, expressed his belief that the spinal cord or brain was not the seat of such lesions. Ten years after Duménil made the first demonstration, Eiehorst ‡ recorded a case in which a post-mortem examination showed the spinal cord to be perfectly sound, but several peripheral nerves presented evidences, both grossly and microscopically, of interstitial inflammation. Then followed Joffroy \* in 1879, Leyden †† in 1880, and Grainger Stewart ^ in 1881, with similar reports. During the past decade the pathological study of peripheral nerves has been pursued with commendable zeal, and upon inflammation of them or its results are now known to depend many forms of paralysis, especially localized ones, numerous sensory disturbances, and various trophic changes in the skin, bones, muscles, and other tissues whose description in detail I must withhold from this paper.

Investigators have also shown that such inflammations and degenerations follow upon certain diseases or certain agencies with a frequency that justifies the regarding of the latter as aetiological factors in the production of the former. Among those which thus act as causes may be mentioned diphtheria, scarlet fever, measles, small-pox, typhus, typhoid, and malarial fevers, *la grippe*, syphilis, tuberculosis, leprosy, diabetes, rheumatism, locomotor ataxy, beri-beri, etc., and such substances as lead, arsenic, alcohol, bisulphide of

carbon, etc. There is also idiopathic peripheral neuritis whose cause is not apparent, which expresses itself in such diseases as herpes zoster, Raynaud's disease, circumscribed sclerodermia (Hutchinson), sciatica, so-called rheumatic paralysis, such as that of the facial, abducens, etc. Again, it may occur from traumatism and pressure. The relation which peripheral neuritis is thus shown to hold to other diseases, both as an effect and as a cause, gives it a far-reaching importance to the diagnostician, therapist, and pathologist.

I desire at this time not only to emphasize this importance, but to indicate also that this disease is not confined to the nerves of motion and general sensation, as is generally understood by the profession, but includes inflammations of nerves of special sense as well, having the same known general causes, as well as arising idiopathically or from unknown causes, and the symptoms of which correspond in character and magnitude with the functions involved. I might with propriety consider inflammations of the olfactory and gustatory nerves, and point out how they may be the sequence of influences not started or found in their end-organs or in the brain, but arising from the same causes as inflammations of other nerves. It is only thus that many affections of smell and taste can be accounted for. So, also, with the nerve of hearing. Certain forms of deafness, tinnitus, and vertigo are undoubtedly induced by typhus and typhoid fevers, measles, scarlet fever, small-pox, mumps, and syphilis, through a peripheral neuritis of the auditory nerve. I will, however, limit this part of my discussion to inflammations of the optic nerve.

The pathology and pathological anatomy underlying many forms of visual disturbances are subjects of comparatively recent study. Before the discovery of the ophthalmoscope the fundus of the eye was clinically an impenetrable region. With this instrument the practitioner has been enabled to reach and study it, and by post-mortem examination has verified the diagnosis of such forms of neuritis as express themselves at the intra-ocular extremity of the optic nerve—the optic disc—by swelling, cloudiness, and change of color. But there are some cases which present the subjective symptoms and clinical history of optic neuritis, but the ophthalmoscope does not show the disc-picture formerly believed to be a necessary accompaniment. As early, however, as 1866, von Graefe,\* of Berlin, whose clear insight and acuteness of observation have never been excelled, suspected that such subjective symptoms were not due to amaurosis (amaurosis was then, as now, a cloak-word for pathological ignorance) or to brain disease, but rather to inflammation of the optic nerve situated behind the ball and showing very little change within the eye, and therefore out of sight of the ophthalmoscopist. He described cases in which vision became clouded and within a few hours or days absolute blindness ensued, and yet the ophthalmoscopic signs were almost negative. Both eyes were symmetrically affected, and the blindness was temporary in some and permanent in others. To this form of disease, acute in character, he gave the name retro-bulbar or retro-

ocular optic neuritis. The diagnosis of the lesion was afterward verified by post-mortem examinations. Later, Leber,\* in 1869, expressed the belief that the symptoms in certain cases of amblyopia with central scotoma, but without any marked changes in the fundus of the eye, were due to a form of chronic inflammation in the orbital portion of the optic nerve. These conjectures were subsequently entertained by other investigators, but it was not till Samelsohn,† of Cologne, in 1880, and Nettleship and Edmunds,‡ of London, in 1881, made the initial post-mortem examinations of cases of central amblyopia that demonstration was actually made of an inflammatory and resulting degenerative process in the course of the optic nerve. In each of these cases there was found "a tract of chronic interstitial inflammation and degeneration extending from the optic foramen, where it was central, to the eyeball, where it occupied the outer part of the optic nerve."§ Similar results were obtained by Vossius,|| of Königsberg, in 1882; Bunge,^ of Halle, in 1884; Uthoff,∞ of Berlin, who made seven autopsies, in 1884 to 1886; and Sæhs,∫ of Innsbrück, in 1887.

Thus it has been conclusively proved that optic neuritis may exist both with and without objective ophthalmoscopic signs and with varying subjective symptoms from mild to aggravated, and in its progress it may be rapid or slow. These symptoms, objective or subjective, I need not detail here. They are clearly before the profession.

In diagnosis, however, proper exclusions should be made in cases where impairment of vision can not be readily accounted for by the ophthalmoscope or other means of examination. Thus, there are various lesions within the encephalon that affect vision without involving the optic nerve—for example, disease of the occipital lobe of the brain. Quinine produces in sufficient doses such disturbance of the circulation of blood in the optic nerve by vaso-motor irritation as to greatly contract the field and diminish the acuteness of vision, either temporarily or permanently. Experimental research by De Schweinitz,∫ of Philadelphia, made during the present year on animals, goes to show that it does not produce neuritis. Atrophy of the optic nerve may undoubtedly take place without a preceding neuritis by some mechanical or vaso-motor arrest or diminution of blood-supply to the nerve.

As causes of optic-nerve inflammation there are many that are common to this and other forms of neuritis. Thus it may be caused by injury, and injury will produce neuritis elsewhere. Contiguous inflammations, such as orbital cellu-

litis or meningitis, may cause it. So may other nerves become involved in the inflammatory processes of surrounding tissues. Pressure from growths or foreign bodies causes inflammation of both the optic and other nerves.

It is well proved and generally admitted that certain substances and poisons produce an inflammation of certain peripheral nerves (peripheral neuritis), prominent among which are alcohol, lead, arsenic, and bisulphide of carbon. These substances, too, produce some form of optic neuritis. To fortify this statement I will cite some authorities. Uthoff,\* of Berlin, has clearly shown that alcohol develops axial or chronic retrobulbar optic neuritis. Hutchinson, † of London, and Allbutt, ‡ of Leeds, are among several who have reported cases of optic neuritis and subsequent optic-nerve atrophy, as shown by the ophthalmoscope, caused by lead within the system. Among those who have seen optic neuritis in chronic arsenic poisoning are Da Costa, § of Philadelphia, and C. L. Dana, || of New York; Nettleship, ^ of London, Fuchs, ¶ of Liege, Galezowski, †† of Paris, and others have seen "axial" optic neuritis (central amblyopia) in persons exposed to the fumes of bisulphide of carbon in the manufacture of certain rubber materials.

Diseases which cause peripheral neuritis also cause optic neuritis. Hulke, ‡ of London, as early as 1868, recorded cases of optic neuritis after diphtheria, and Allbutt † and others have made similar observations. Wadsworth,\*\* of Boston, and others have seen optic neuritis after measles. Macnamara, †† of London, has reported cases in which optic neuritis developed in rheumatism and intermittent fever. He has also seen this disease in *la grippe*, ††† and so also have Weeks, ††† of New York, and others. The history of the recent epidemics of *la grippe* furnishes many examples of "peripheral palsies." Typhoid and typhus fevers, smallpox, scarlet fever, syphilis, tabes, tuberculosis, and diabetes stand out more or less prominently in their ætiological relations to peripheral neuritis. Optic neuritis also is found in each of them in corresponding frequency. Lastly, both peripheral and optic neuritis occur alike idiopathically without any assignable cause.

I might multiply illustrations showing the common origin of both so-called peripheral neuritis and optic neuritis in some of their varieties, but it seems to me that the evidence already adduced is sufficient to place beyond doubt the claim that certain ætiological influences and pathological

results are common to both, the symptoms varying only in correspondence to difference of function of the nerve or nerves affected.

We can not, perhaps, understand why alcohol, bisulphide of carbon, tobacco, or diabetes should induce axial or chronic retro-bulbar neuritis, while lead, arsenic, diphtheria, tabes, *la grippe*, or measles should develop a neuritis more generally interstitial, often acute, and showing ophthalmoscopic signs. Neither can we offer satisfactory explanation why lead pre-eminently affects the nerves supplying the extensor muscles of the extremities and the muscles of the intestine, or why tobacco has a special affinity for the nerves going to the heart, or why diphtheria conspicuously leaves its impress upon the cranial motor nerves and some of the spinal. Yet such facts remain, and the lesson which they teach us to-day is that inflammation may attack all classes of peripheral nerves alike, those of special sense as well as those of general sensation and motion, that the cause is wide-spread and common, and that the principles of treatment are identical.

Peripheral neuritis in its broadest sense, therefore, becomes of intense interest and far-reaching importance to both the general practitioner and specialist.

## VERTIGO.\*

By EDWIN R. MAXSON, M. D., A. M., LL. D.,  
SYRACUSE, N. Y.

VERTIGO—from *verto*, I turn—implies giddiness, dizziness, swimming of the head, and may be produced by a variety of causes, operating through different parts of the system. And hence we have it as a consequence of gastric, epileptic, migrainous, and gouty affections; organic, brain, and spinal disease; and certain affections of the eye and ear.

*Gastric* vertigo, being very common, may generally be recognized, depending, as it does, upon various forms of indigestion.

*Nervous* vertigo usually attends nervous exhaustion, and generally is, or may be, caused by anxiety, sexual excesses, tobacco, and tea or coffee.

*Epileptic* vertigo may occur in a fit of epilepsy, or even take the place of it; quite frequently preceding. Hence it is easily recognized and traceable to the causes operating to produce that disease.

*Migrainous* vertigo, usually constituting one of the phenomena of migraine, either attending or following the development of the headache, or even sometimes replacing it, may readily be understood.

*Gouty* vertigo occasionally occurs in gouty persons, disappearing, perhaps, when there is the supervention of gouty arthritis, by which it may readily be recognized through whatever part it may directly operate.

*Brain* and *spinal* vertigo, of an organic character, may arise from tumors, sclerosis, or other changes of the brain, cerebrum or cerebellum, or spinal cord. It is generally

attended by symptoms pointing to the seat of the disease, cephalic or spinal.

*Ocular vertigo*, depending, as it may, upon a paralysis or weakness of one or more of the recti muscles, etc., causes an incorrect notion of objects. And hence a sense of confusion and giddiness occurs, rendering a fairly plain indication of the seat of the disease.

*Aural vertigo*, however, may not be as readily recognized. It has been variously named labyrinthine, apoplectic, and Ménière's disease—this last from his description of it in 1861. Under these headings have been classed cases in which vertigo, with various other symptoms, is caused by disease of the labyrinth directly, as congestion, inflammation, or "hæmorrhage; or indirectly by disease of the middle ear, Eustachian obstruction, spasm of the tensor tympani, or paralysis of the stapedius, or irritation or obstruction of the external meatus, and pressure on the membrana tympani, as by cerumen, foreign bodies, or by syringing the ears, especially when the membranes are perforated" (Stephen Mackenzie).

Thus the labyrinthine affection may be either primary or secondary, "irritative or destructive."

It has been stated by Farrier that the dizziness tends to falling, in cases not primarily labyrinthine, in one direction; and in the primarily labyrinthine in the opposite. But in all cases the cochlea and semicircular canals are involved, attended with vertigo, tinnitus, and vomiting, with some degree of deafness in most cases of primary labyrinthine origin. And in these cases the vertigo is related to the change in the position of the head, being aggravated by one position and relieved by another, according to the canal more especially affected. And, in the primary cases, there may be more generally falling and obstinate vomiting.

In all cases of Ménière's disease there is more or less secondary visceral disturbance, such as pallor, faintness, nausea and vomiting, syncope, etc. This is doubtless owing to the proximity of origin of the auditory nerve (a branch of which, the *vestibular*, supplies the semicircular canals) to the *pneumogastric*. And, further, the blood supply of the labyrinth from the vertebral artery comes from the subclavian, near the inferior cervical ganglion of the sympathetic, by which ganglion not only the vestibular artery is thus supplied, but it also "sends communicating branches to the pneumogastric and branches to the heart," thus connecting, in sympathy, the labyrinth with the heart, stomach, "and other organs," accounting for the nausea, vomiting, faintness, or syncope, etc., as well as tinnitus and dizziness, characteristic of Ménière's disease, as suggested by Mackenzie.

*Symptoms*.—This disease may come on quite suddenly, perhaps with a noise in the ear, but not invariably.

In one case, that of a gentleman of sixty, he had formerly suffered from some aural disease; and though apparently in about his usual health (which was habitually feeble), he may have had a slight congestive chill, perhaps, or incipient influenza (*la grippe*). At any rate, he suddenly became unable to stand with his head erect, and, being up a flight of stairs, he had to come down with his head bowed down; and to walk with his head thus bowed or else lie down, as

he assured me when I saw him three weeks later, being out of the city. He, as is usual with the dizziness, on raising his head, had some nausea and vomiting, and he could not stand erect with stability.

The *noise*, if heard, is in one ear; and the apparent or real movements of the body are in a direction opposite to the affected ear, as I have witnessed; the falling, when it takes place, being "more frequently forward, or to one side," according to Mackenzie.

In another case the patient, a young lady of eighteen, who had formerly suffered from some slight aural affection, while having the mumps, being engaged in hard study, sleeping in, or adjoining to, a recently plastered room, not entirely dry—having also some symptoms of influenza (*la grippe*), without any appreciable noise in the ear—became unable to raise her head without producing vertigo, nausea, and vomiting, necessitating the recumbent posture, there being no stability in standing.

Some secondary cases of this disease may be transient, lasting only a short time. But the vertigo may persist, with or without the vomiting, or it may recur.

In cases in which the labyrinthine disease is primary, however, it may continue for many months, reducing the patient almost to a skeleton, as occurred in one case that fell under my observation away from this city. The case had been treated in the main, I believe, as of gastric origin. I doubt if the patient recovers, from the last accounts, though he may.

In another case, early diagnosticated and properly treated, the patient has recovered and remains in excellent health, though apparently more severe than the one above referred to.

And still another of several months' standing, the primary symptoms having apparently been quite obscure, the sympathetic neurotic predominating, terminated fatally, probably by an extension of the labyrinthine disease to the brain.

The three cases were evidently primary labyrinthine disease.

The symptoms of secondary Ménière's disease usually subside, as the Eustachian, tympanic, and other primary aural affections and obstructions are relieved and removed, as they may generally be, one of which I have recently seen in this city.

*Diagnosis*.—The diagnosis of Ménière's disease from the gastric, nervous, epileptiform, gouty, organic brain and spinal disease, and ocular affections also attended with vertigo, is not very difficult. For, in addition to the symptoms in common, labyrinthine affections in Ménière's disease have "the vertigo in relation to change in the position of the head," as claimed by Mackenzie, and as I have witnessed in several cases.

To distinguish between a primary and secondary labyrinthine case, the absence of any tympanic, Eustachian, or external auditory disease or obstruction may generally lead to a correct conclusion (von Tröltzsch).

It may be well to remember that deafness and tinnitus without vertigo, or vertigo and tinnitus without deafness, may be due to affections of the middle ear, while vertigo,

tinnitus, and deafness indicate an affection of the labyrinth (Maekenzie).

*Pathology.*—As it has now become quite well established by experimental observations and research in disease, by “Flourens, Cyon, Crum Brown, and others” (*Quain*), “that the semicircular canals take an important share in normal equilibration, injury and disease of these parts occasioning locomotive inco-ordination,” it is evidently from this disturbance that the vertigo exists.

There is also in primary cases congestion, inflammation, or hæmorrhage involving the labyrinth, while in secondary cases there is irritation, at least, from sympathy with disease of the tympanum, meatus, Eustachian tube, or other labyrinthine auricular parts or structures.

The vertigo may be caused directly by “variations in the blood-pressure,” as held by Maekenzie, and, together with all the symptoms of this disease, may be owing to consequent variations in the tension of the membranous semicircular canals, changes in the pressure of the endolymph and perilymph, transmitting an influence through the auditory and sympathetic nerves to the cerebro-spinal and ganglionic systems, thus accounting for all the phenomena of this disease, primary and sympathetic.

The membranous vestibule and cochlea doubtless aid through the same systems of nerves in developing the local and sympathetic symptoms of this disease, but perhaps in a less degree, so far as relates to the dizziness.

*Prognosis.*—In cases in which the labyrinthine affection is not primary, but owing to some remediable defect in the tympanum, external meatus, or Eustachian tube, a recovery may generally be expected under judicious treatment directed to the primary disease.

In primary labyrinthine cases the disease, under judicious treatment, may be greatly relieved, if not cured, though a degree of deafness and tinnitus may remain in some cases, or recur. But, if neglected or improperly treated, suppuration in the labyrinthine membranes may extend along the vestibular “tubular prolongation” and *cul-de-sac* of the *aqueductus vestibuli*, through the posterior petrous wall or otherwise, to the cranial cavity, and dangerously involve the brain, as I suspected did occur in one case that fell under my observation.

*Treatment.*—The treatment of *gastric* vertigo involves a strict regulation of the diet and habits of the patient to favor digestion. Proper food, with strict regularity and suitable drinks, must be enjoined, as well as avoidance of all trash. Tonics to aid digestion may be required, and, in some rare cases, counter-irritants.

*Nervous* vertigo calls for prudence in sexual and other indulgences; avoidance of alcohol, opium, and tobacco; and a strict observance of the laws of health in every respect. Regular hours for sleep must be strictly enjoined and observed. It requires also good substantial food to be taken with strict regularity, and may require the substitution of hot water instead of tea and coffee in some cases.

*Epileptoid* vertigo requires the general treatment proper for epilepsy, which consists in regulating all the habits and administering blood and nerve tonics, the most effectual of which, according to my observation, are oxide of zinc, car-

bonate of iron, and rhubarb, two grains of each for an adult, three times a day. And if the epilepsy or tendency to it is cured, the vertigo disappears.

For *migrainous* vertigo a regulated diet, tonics, and an occasional dose of magnesia when there are approaching symptoms, may do best. Correction of imperfect ocular action may be attended to if indicated.

In *gouty* vertigo, colchicum, guaiac, and iodide of potassium may be indicated, and moderation in eating and drinking insisted upon.

In cases depending upon *organic, brain, or spinal* disease—as tumors, sclerosis, etc.—a regulated diet and iodide of potassium, in full doses, may do best. Wet cups may be indicated to the back of the neck, and blisters back of the ears, and later to the back of the neck, should be persevered in to the last. Mercurials may become necessary in some cases. If so, I prefer the bichloride in solution with the iodide of potassium, about eight grains of the iodide and a twelfth of a grain of the mercurial, well diluted when taken—forming, of course, an iodide of mercury.

For *ocular* cases, in addition to correcting all the habits, suitable treatment should be addressed to whatever defect there may be in the eye, or its muscles or appendages. Cups to the back of the neck and blisters back of the ears and to the temples, electricity, and possibly the adjustment of glasses, may be required.

The indications in the treatment of *aural* vertigo (*Ménière's disease*), in which the labyrinthine affection is not primary, depending upon disease of the tympanum or external meatus, or obstruction of the Eustachian tube, should be adapted to the condition in each particular case.

It may involve cups or blisters to the back of the neck, leeches or blisters back of the ears and to the temples, syringing the external meatus to remove wax, or using the Eustachian catheter to clear that tube, and possibly the dropping into the external meatus a solution of twenty grains of boric acid to the ounce of equal parts of glycerin and water, daily, for catarrh of the meatus, and electricity for paralysis of the stapedius muscle.

The treatment of *primary* labyrinthine disease includes several indications. Cups should be applied early to the back of the neck, and repeated, if necessary; and at first leeches to the mastoid process and temples. Later, blisters may be substituted and repeated, if necessary, while the vertigo, nausea, or vomiting remains. The ammoniated citrate of bismuth, in one-grain or two-grain doses, may be given three times a day, to allay sympathetic gastric derangement. And, to favor digestion, two drops of the tincture of *nux vomica* may be required.

In anæmic, congestive, or malarious cases, two or three grains (*not more*) of cinchonidine may be required every six hours, alternating with the bismuth and *nux vomica*, and possibly bromide of potassium at evening.

The feet should be set in warm water daily, and magnesia may be given each morning to avoid constipation and as an antacid; and, if the tongue is coated, an improved cathartic or leptandrin pill at evening till it becomes clean. Toast and egg may be allowed at meal time, and

hot toast-water and milk given for drink at all hours if desired.

The worst case I have seen was, under this treatment, quite well in about four weeks, and has remained so, having gained ten pounds of flesh in a few weeks, and is enduring close study.

Another case which was at first, as I learned, regarded as gastric, and later as "neurasthenia," really an effect of the un cured aural disease, has now been suffering for several months, with little prospect, I fear, of a cure or even much improvement, as nearly as I can learn, emaciation and debility having become extreme, evidently from the non-removal of the original labyrinthine affection, the aural disease and sympathetic visceral derangements having evidently seriously impaired digestion, thus in a large degree cutting off nutrition.

Still another case of longer duration, having been regarded and treated as ocular, epileptiform, and organic brain disease, which it doubtless at length became—suppuration occurring in the labyrinthine membranes and extending to the brain eventually led to a fatal termination.

The auricular disease early appears to have been rather obscure, and in the latter stages, as is usual, very much obscured by the consecutive brain disease and sympathetic visceral derangements; and, while a clear diagnosis was not made, it was the expressed opinion of the last attendant from the first that there might be an obscure organic brain disease, and that, if so, it would terminate fatally. And this was, I believe, concurred in by others at the last, though opinions may have differed as to the character of the organic brain disease somewhat.

It may not be improper to add, in conclusion, that since writing this I have received from a lady of sixty, at a distance, an account of her having been taken, two years ago, with "dizziness, some vomiting, finally had to give up, was in bed several weeks," etc. She adds that since, there is a "buzzing" (*tinnitus*) "in the left side of the head, followed by a whirling, dizzy feeling; has to stop and hold on to something and shut her eyes till it passes off, perhaps twenty times a day."

She further stated that she had not got anything to help her head, that she "feels weak and trembles all the time," etc. She closed by expressing a hope that I could help her. A later examination confirmed the suspicions her letter had produced of labyrinthine disease. And I further learned that it may have originated in influenza (*la grippe*), constituting the fourth case I have been able to trace to that disease, more or less directly, of late.

818 MADISON STREET.

**Influenza Colds.**—"Few remedies are more reliable, and act better as a preventive, or lessen the distressing symptoms of an influenza cold, than the following mixture:

℞ Sodii salicylas..... ʒ jss.;  
 Liq. ammon. acet..... ʒ ij;  
 Aq. camph..... ad ʒ vj.

Misce. Capt.: ʒ ss. omnis 3tiis horis.

If this be taken every two or three hours when the first symptoms of cold come on, it will usually ward off the attack."—*British and Colonial Druggist*.

THE

NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by  
 D. APPLETON & Co.

Edited by  
 FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JANUARY 23, 1892.

FLOATING KIDNEY AND NEPHRYDROSIS.

In the September, October, and December numbers of the *Revue de chirurgie* there is to be found an exhaustive article on intermittent nephrydrosis (*hydronéphrose intermittente*) by M. Félix Terrier and M. Marcel Baudouin. There exists, say these authors, a variety of nephrydrosis, not well understood until within recent years, that seems to be commoner than has been supposed; it is an intermittent nephrydrosis. Very often it is the first stage of a confirmed nephrydrosis. It is due to lesions of various sorts; in the great majority of cases it occurs as a complication of renal displacements, wherefore it is observed oftener in women than in men. In the former it is met with especially on the right side; in the latter, on the left. More rarely it may be the consequence of a calculus in the pelvis of the kidney or of temporary compression or obliteration of the lower end of the ureter. In some cases it is of congenital origin.

When it is a complication of floating kidney it is produced in the following way, as shown by experiment and by post-mortem appearances: An abrupt bending of the ureter occurs, with or without torsion, at the same time with renal displacement; there is a temporary arrest of the flow of urine, with the progressive development of a nephrydrotic sac, which empties itself as soon as the kidney resumes its place; irritation arises around the renal pelvis, either from embarrassment of the circulation or from infection of the mucous membrane of the pelvis; and fibrous adhesions unite the sac to the upper part of the ureter, and finally lead to the transformation of the intermittent into a confirmed nephrydrosis. These alternations of distention and evacuation of the renal pelvis, consequent on temporary obliteration of the ureter, are manifested clinically by attacks of pain that are well-nigh characteristic, occurring in the course of a state of health more or less deranged, about once a month and sometimes oftener. These attacks, which present three stages—the onset, the acme, and the decline—are constituted by extremely intense pains, sometimes absolutely intolerable, coinciding with the appearance of a liquid tumor, rarely fluctuating, seated most commonly in the right flank, and with a notable decrease of the amount of urine voided. They are the result of a sharp bend in the ureter in consequence of the displacement of a movable kidney. The attack lasts for a number of hours, and ceases suddenly when the kidney resumes its normal situation. The tumor disappears with the pains, and a considerable discharge of urine ensues—the pelvis of the kidney empties itself.

At the last meeting of the British Medical Association, before the Section in Surgery, Mr. R. Clement Lucas made

remarks to much the same purpose. Mr. Lucas's remarks are published in the *British Medical Journal* for December 26th. His conclusions are as follows: Movable kidney is a condition that during displacement may, and often does, lead to nephrydrotic destruction, owing to twisting of the pedicle or to pressure of the organ upon its duet; to avoid such danger and to relieve the patient from pain, all such cases should be treated by nephrorrhaphy, which is a simple and safe operation; even when nephrydrosis has already advanced, cases in which it is clearly due to the mobility may be cured by nephrorrhaphy, and the remains of the organ saved from further degeneration.

#### DRUNKENNESS SUCCESSFULLY COMBATED IN NORTHERN EUROPE.

A FAIR measure of success has crowned the temperance legislation of Sweden and Norway. These northern peoples have been the pioneers in the successful management of that threatening visitant leprosy, which by governmental effort has been shorn of some of its harmful powers. They are now showing the way in which the baneful drink-habit may be checked, which has prevailed to an alarming extent among all classes. The larger towns have been led to put "local option" in force, and their efforts have been even more successful than was expected. The Earl of Meath, says the *Medical Press and Circular* for December 16th, has lately returned from a visit to the Scandinavian peninsula, and reports that "the maximum of good to the community has already been effected with the minimum of inconvenience to all classes." The system known by the name of the "Gothenburg system" was first experimented with, but it was attended with so much friction and ill-will that it soon gave place to other methods, one of which is the municipal "trading society" licensing method.

The municipal council decrees the number of licenses that is equal to the reasonable requirements of the population. A monopoly is then given to a society formed by the trading community, and for a definite term of years. The council retains full control of the operations of the society. No private person is allowed to retail spirituous liquors. The retailing of beer and wine is permitted under a special license. A certain proportion of the profits is applied to pay the shareholders of the society their preferential interest, after which the surplus must be assigned to charitable societies and institutions. Last year there were fifty of these societies in operation. In nearly all of these localities the same general restrictions exist as to hours of sale and persons who may buy; all licensed houses must shut down from 8 P. M. on Saturday until 8 A. M. on Monday, and no person under sixteen years of age may be served with alcoholic drink, no person under intoxication may be served, and no female bar-tenders are permitted. The society of the city of Bergen in Norway has been enabled to show a net profit of fully one hundred and twenty-five per cent., which is an indirect gain to the public in its charitable work and in the repression of inebriety that is found to be incalculable. Brawls,

and wounds, and deaths by violence have been reduced, while the resources for the hospital treatment of the deserving poor have been increased.

#### MINOR PARAGRAPHS.

##### A BALL OF HAIR IN THE HUMAN STOMACH.

VON BOLLINGER reports a case in one of the September numbers of the *Deutsche Medicinal-Zeitung* which presents some peculiar features. The patient, a girl sixteen years of age, had been for three or four years a sufferer from severe pain in the stomach, with vomiting. These symptoms increased in intensity until nutrition was so materially interfered with that life could not be prolonged. Before death a firm tumor in the region of the stomach could be demonstrated, and a diagnosis of malignant growth in that organ was made. The autopsy revealed the stomach and duodenum very much enlarged, measuring about twenty inches in length and ten in circumference, and apparently filled with some hard substance. On opening the stomach, it was found to be packed with hair, which extended down into the duodenum for three or four inches, the entire mass being so firmly wedged into the parts that it was with difficulty removed in its entirety. The mucous surface of the stomach was much softened and covered with a thick grayish fluid which contained fat crystals, sarcinae, spores and mycelium of mold fungus, and also some starch granules. Inquiry into the history of the case failed to elicit anything that would point to the patient's having swallowed hair at any time. Schönborn, in 1883, reported a similar case in which he did a laparotomy and opened the stomach of a girl fifteen years of age and removed a quantity of hair.

##### THE DIGESTIBILITY OF CHEESE.

It is the general opinion of the laity that the eating of cheese after taking food is an assistance to digestion. This view seems not to be in accord with the result of experiments made by von Klenze, as recorded in the *Allgemeine medicinische Central-Zeitung*, No. 18, 1891. He made very thorough tests of the various forms of cheese found in the dietary lists. For the experiments he used an artificial digestive fluid, to which were added 50 c. c. of fresh gastric juice and 3 c. c. of hydrochloric acid. Into this he placed a gramme of the cheese to be examined. Eighteen varieties were tested, and the following deductions made: Chester and Roquefort cheese took four hours to digest; genuine Emmenthaler, Gorgonzoler, and Neufchatel, eight hours; Romadour, nine hours; and Kottenberger, Brie, Swiss, and the remaining varieties, ten hours. Considering that in a healthy stomach digestion after an ordinary meal is complete in from four to five hours, it would seem from von Klenze's studies, that Chester and Roquefort cheese were the only kinds that were likely to be digested within this length of time, and that the other varieties, some of which are largely in use, not only did not assist digestion, but actually retarded it.

##### PAGET'S DISEASE OF THE GLANS PENIS.

PROFESSOR PICK, in the *Medicinisch-chirurgische Rundschau* for December, 1891, reports the case of a patient who came to him suffering from the following symptoms: For eighteen months there had been an obstinate eczema of the glans penis. There was also a tendency to proliferation of the epithelium and to nodular formation around the glans. An operation for phimosis was called for, and this resulted in temporary improvement of the eczematous condition. The nodular infiltration, however,

returned in a short time. Microscopical examination of a portion of the growth showed it to contain cancer cells and numerous psorosperms. With the exception of the presence of the psorosperms, the whole course of the disease, from the initial obstinate eczema to the cancerous degeneration, was one of typical Paget's disease, such as has been described as occurring in the breasts, the only difference in this case being in the seat of the disease. What part the micro-organisms played in the disease it was difficult to say, but the author thought that they should be looked for in other suspicious cases of the sort.

HELENIN IN THE TREATMENT OF LEUCORRHOEA.

In the *Archives de toxicologie et de gynécologie* for December M. Hamonic relates his experience with helenin as a remedy. He has found it worse than useless in gonorrhœa, but capable of curing cervical leucorrhœa, even without topical treatment. He prescribes the following formula: Crude helenin, inulin, each, 15 grains; sugar of milk, q. s. Mix, divide into 100 pills. From two to four to be taken daily. The inulin is said to have no remedial power, and to be replaceable by powdered licorice or conserve of roses. Used as an injection, inulin simply irritates the vagina.

IN HONOR OF ANTONIO SCARPA.

SCARPA's place in history has been apparently neglected. But, according to the *Medical Press* for January 6th, the people of Pavia have awakened to the propriety of constructing some permanent public memorial of their great Antonio Scarpa. The citizens' committees will receive contributions from foreign anatomists and others, to the end that Scarpa's space at Pavia may be appropriately adorned.

THE INTERNATIONAL MEDICAL MAGAZINE.

A new monthly journal of this name has been announced to appear in January, published by the Lippincott Company, of Philadelphia. Forensic medicine is to be made one of its special departments.

ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending January 19, 1892:

DISEASES.	Week ending Jan. 12.		Week ending Jan. 19.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	9	2	9	6
Scarlet fever	223	33	242	33
Cerebro-spinal meningitis	1	3	4	2
Measles	132	12	152	9
Diphtheria	128	46	115	46
Small-pox	0	0	0	0
Erysipelas	2	0	2	0
Varicella	16	0	9	0
Pertussis	0	8	0	2
Mumps	0	0	0	0

**The New York County Medical Association.**—At the recent annual meeting officers for the ensuing year were elected as follows: President, Dr. S. B. Wylie McLeod; vice-president, Dr. William T. White; recording secretary, Dr. P. Brynberg Porter; corresponding and statistical secretary, Dr. Augustus D. Ruggles; treasurer, Dr. John H. Hinton; member of the executive committee, Dr. Beverhout Thompon. The association now has a membership of over seven hundred.

**The Alvarenga Prize of the College of Physicians of Philadelphia.**—The college announces that the next award of the Alvarenga prize, being the income for one year of the bequest of the late Señor Alva-

renga, and amounting to about one hundred and eighty dollars, will be made on July 14, 1892. Essays intended for competition may be upon any subject in medicine, and must be received by the secretary of the college on or before May 1, 1892. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the college.

**The New York Pathological Society.**—At the next meeting, on Wednesday evening, the 27th inst., Dr. Francis Delafield will illustrate the lesions of the different forms of Bright's disease by photomicrographs projected on the screen.

**The New York Surgical Society.**—At the next meeting, on Wednesday evening, the 27th inst., Dr. Wyeth will read a paper on Ether Narcosis as induced by the Ormsby Inhaler.

**A Misquotation.**—An esteemed correspondent calls our attention to the fact that, in an article published in the *Journal* for January 9th, on page 42, the expression *facilis descensus Averni* was incorrectly printed "facile descensus Averno."

**New Remedy for Phthisis.**—The latest remedy for phthisis is monochlorophenol. It is described as a powerful antiseptic, free from the disagreeable odor and from the caustic and irritant action of its related compound, trichlorophenol. It has been introduced by Tæchini, a chemist of Pavia, and successfully tried by several Italian doctors. It is recommended as an inhalation in various affections of the respiratory passages, and especially in pulmonary tuberculosis. Monochlorophenol is very volatile, giving off heavy vapors on heating, which are antagonistic to bacilli.—*British and Colonial Druggist.*

**The Death of Dr. Henry Ingersoll Bowditch, of Boston,** took place at his home, in that city, on Thursday, the 14th inst. The deceased was in his eighty-fourth year. For many years, as a teacher, as a practitioner, and as a participant in matters pertaining to the welfare of the profession as a body, he had been a prominent figure. Perhaps he was best known for his active part in perfecting and popularizing the operation of paracentesis thoracis and for his elaborate researches on telluric conditions as factors in the ætiology of pulmonary consumption. Nobody in the American profession was more highly esteemed than Dr. Bowditch.

**The Death of Dr. Daniel Ayres, of Brooklyn,** in his sixty-ninth year, occurred on the 18th inst., after an illness of two weeks. As a surgeon and pathologist, Dr. Ayres held a high rank. He took a lively interest in the City Hospital and in the Long Island College Hospital at the time of their inception. He was a liberal donor to the Hoagland Laboratory and the Wesleyan University, the latter institution receiving from him gifts of lands and money valued at nearly \$375,000. He was honored with the degree of LL. D. by that institution in 1865. He was a frequent contributor to the journals, and was a clear and cogent teacher of surgery and surgical pathology.

**The Death of Dr. Charles Martin, of the Navy,** a medical director on the retired list, took place in New York on Thursday, the 14th inst. He had been a medical officer of the navy since 1848.

**The Death of Dr. Colin Mackenzie,** on Saturday of last week, deprived the New York profession of one of its most estimable members. Dr. Mackenzie was a graduate of the Cleveland Medical College, of the class of 1860, but most of his professional life had been spent in New York.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 3 to January 16, 1892:*

GLENNAN, JAMES D., First Lieutenant and Assistant Surgeon, is granted leave of absence for one month on surgeon's certificate of disability, with permission to go beyond the limits of the department.

KEAN, JEFFERSON R., Captain and Assistant Surgeon. The leave of absence granted on surgeon's certificate of disability is extended three months on account of sickness.

PATZKI, JULIUS H., Major and Surgeon, and BURTON, HENRY G., Captain and Assistant Surgeon, having been found incapacitated for active

service by the Army Retiring Board, will proceed to their homes, and on arrival there report by letter to the Adjutant-General of the army.

KIMBALL, JAMES P., Major and Surgeon, is granted leave of absence for six months, with permission to go beyond the sea, to take effect on or about January 27, 1892.

O'REILLY, ROBERT M., Major and Surgeon, Fort Logan, Colorado, is granted leave of absence for twenty-one days.

KILBOURNE, HENRY S., Captain and Assistant Surgeon, is relieved from duty at Willett's Point, New York, and will report in person to the Superintendent of the U. S. Military Academy, West Point, New York, for duty at that station, relieving W. Fitzhugh Carter, Captain and Assistant Surgeon. Upon being relieved by Captain Kilbourne, Captain Carter will report in person to the commanding officer, Willett's Point, for duty at that station.

PATZKI, JULIUS H., Major and Surgeon, having been found, by the Army Retiring Board, incapacitated for active service on account of disability incident to the service, is, by the direction of the President, retired from active service, to take effect January 9, 1892, under the provisions of Sec. 1251, Revised Statutes.

FISHER, WALTER W. R., Captain and Assistant Surgeon, is granted leave of absence for one month.

WOOD, MARSHALL W., Captain and Assistant Surgeon, now on leave of absence, will report to the commanding officer, Fort Columbus, New York, for temporary duty at that post during the absence of Captain W. W. R. Fisher.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the two weeks ending January 16, 1892:*

PIGOTT, M. R., Assistant Surgeon. Detached from the Naval Hospital, Mare Island, Cal., and ordered to the U. S. Steamer Baltimore.

STITT, E. R., Assistant Surgeon. Detached from the U. S. Steamer Baltimore, ordered home, and two months' leave of absence granted.

GUEST, M. S., Assistant Surgeon. Ordered to the Navy Yard, Norfolk, Va.

WHITE, C. H., Medical Inspector. Detached from the U. S. Steamer Charleston, to proceed home, and two months' leave granted.

PARKER, J. B., Surgeon. Ordered to the U. S. Steamer Charleston.

PARKER, J., Surgeon. Ordered to the U. S. Steamer Charleston.

WHITE, C. H., Medical Inspector. Detached from the U. S. Steamer Charleston and ordered home.

LUNG, GEORGE A., Assistant Surgeon. Ordered to examination for promotion.

BRYANT, PATRICK H., Assistant Surgeon. Ordered to examination for promotion.

VON WEDEKIND, LUTHER L., Assistant Surgeon. Ordered to examination for promotion.

#### Society Meetings for the Coming Week:

MONDAY, *January 25th*: Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

TUESDAY, *January 26th*: New York Academy of Medicine (Section in Laryngology and Rhinology); New York Dermatological Society (private); Buffalo Obstetrical Society; Medical Societies of the Counties of Onondaga (semi annual—Syracuse) and Putnam (semi-annual), N. Y.; Boston Society of Medical Sciences (private).

WEDNESDAY, *January 27th*: New York Surgical Society; New York Pathological Society; Metropolitan Medical Society (private); American Microscopical Society of the City of New York; Medical Society of the County of Albany, N. Y.; Auburn, N. Y., City Medical Association; Berkshire, Mass. (Pittsfield), and Middlesex, Mass., North (Lowell) District Medical Societies; Gloucester, N. J. (quarterly), County Medical Society.

THURSDAY, *January 28th*: New York Academy of Medicine (Section in Obstetrics and Gynecology); New York Orthopaedic Society; Brooklyn Pathological Society; Roxbury, Mass., Society for Medical Improvement (private).

## Letters to the Editor.

### QUANTITATIVE TESTS FOR UREA.

BROOKLYN, *January 18, 1892.*

*To the Editor of the New York Medical Journal:*

SIR: Permit me a few words in reply to the letters of Dr. E. H. Bartley and Dr. J. M. Van Cott, Jr., published in the *Journal* of January 16th, and referring to my paper on Quantitative Tests for Urea.

Dr. Bartley's criticism of my employing a cork in the use of his apparatus instead of the thumb, as he directs, is a just one, and I admit that he is right, the readings being too high by just so much of the scale as is taken up by the cork. I fully intended to make this correction later in connection with a further paper on ureametry, which I have not had the time as yet to write, and I regret the unintentional injustice done to the doctor's apparatus. The doctor omitted to state in his letter that the reason why I found the pressure in the tube too great to withstand was because the tube was two or three inches shorter than it should be and than the ones he is in the habit of using. I obtained the tube from the original makers, Eimer & Amend.

His further statement that I only obtained 1.65 per cent. of urea from a two-per-cent. solution by employing his solution is erroneous, as this has reference only to the use of a solution of one ounce of bromide of potassium to three of chlorinated soda in Doremus's apparatus and not in his. The paragraph in my paper which contains this statement occurs in the course of the description of Doremus's apparatus, and has no reference to Bartley's apparatus.

The criticism of Dr. Van Cott is partly answered with the last explanation. I only used his name as authority for the statement that the use of a solution of one ounce of bromide of potassium in three of chlorinated soda in Doremus's apparatus yielded 1.65 per cent. of urea of a two-per-cent. solution employed, and this he admits is correct.

The other points which he mentions are not a criticism on my paper, but they should have been offered as an improvement on the method employed by Doremus. The solution of bromide of potassium can not be used in Doremus's apparatus under the instructions as given by its inventor. If Dr. Van Cott's suggestion, as stated at the meeting where my paper was read, to fill the bulb of the apparatus with water after the first evolution of gas has ceased, and then close its opening with the thumb and thoroughly agitate the fluids in the long arm, proves to be correct, then this is an improvement and an addition to my statements, but it is not properly a criticism on my paper.

J. C. BIERWIRTH, M. D.

## Proceedings of Societies.

### HARLEM MEDICAL ASSOCIATION.

*Meeting of October 7, 1891.*

The President, Dr. M. C. O'BRIEN, in the Chair.

(*Dr. Arthur H. Leary, Secretary.*)

**Longevity of the Tubercle Bacillus; a Convenient and Rapid Method of coloring the Organism.**—Dr. HENRY HEIMAN read a paper on this subject. (To be published.)

Dr. R. VAN SANTVOORD said that there was an evident necessity of thoroughly mixing the antiseptic fluid, such as the bi-chloride, with the expectorated material from a phthisical pa-

tient. The tubercle was often inclosed in hard and tenacious masses, which were often with difficulty attacked by the disinfecting material. An alkaline solution was of benefit to help disseminate the masses. He was in the habit of employing a process in staining the *Bacillus tuberculosis* with a fuchsin solution containing five per cent. of carbolic acid, decolorizing and staining it simultaneously with a thirty-three-per-cent. solution of sulphuric acid and methylene blue.

The PRESIDENT said that it was his opinion that all tubercular glands found in scrofulous children should be extirpated and the parts thoroughly cleansed with disinfecting solutions. This procedure might prevent general phthisis later in life. He advised patients suffering from phthisis to employ powders or tablets of bichloride to make solutions themselves to disinfect the sputum. It was a noteworthy fact that a large number of internes of the large hospitals died of phthisis. While he was in Bellevue Hospital it was a custom of some of the young doctors to employ hypodermics of ether, etc., in patients in the third stage of phthisis, and then wait to see how long it took to detect the odor in the breath. They thereby had run great risks of contracting the disease. Three of the young men with him in the hospital at that time had died of phthisis a few years later.

Dr. E. L. COCKS said that he frequently pressed the cheesy material between two slides, so as to distribute it evenly and the more readily discover the *Bacillus tuberculosis*. Considering the ease and rapidity with which this bacillus might be stained and demonstrated, physicians were placed in very responsible positions toward their patients. It was their duty to examine the sputum in doubtful or suspected cases. A child seven years old had come under his observation with very few symptoms except gastric disturbance. She had been able to play around the room as usual. Within a few hours, however, strabismus had developed, the head had been thrown backward, followed by convulsions and death. The post-mortem had shown acute tuberculosis throughout all the serous membranes. In the lungs there had been a number of cheesy masses.

Dr. HEIMAN said, in reply to Dr. Martin, as to whether he had found the *Bacillus tuberculosis* present in any case where there were no physical signs, that he had so found the bacillus in these cases. He then made mention of a case in which pulmonary hæmorrhage had been the first premonition of trouble; here a careful search had revealed the bacillus.

Dr. E. MAYER said that he would like to mention an interesting case. A middle-aged woman had complained of hoarseness and slight cough, fever, and general malaise. There had been no positive subjective symptoms of phthisis. The pharyngeal wall had been very pale, a condition frequently noted in phthisis, and was said to be almost pathognomonic. The arytenoid cartilage had been thickened and œdematous, and in one place an ulcerated condition had existed. The sputum had been examined and bacilli had been found. The physical examination of the lungs had been negative.

Dr. F. VON RAITZ said that a case had come under his observation where there had been slight cough and hectic, but absolutely no physical signs of phthisis could be found. But bacilli had been found in the sputum and the patient had died four months later of pulmonary tuberculosis.

Dr. W. F. MARTIN remarked that it was his belief that boiling water placed in the cuspidor of phthisical patients would answer a very beneficent purpose. This would disinfect the mass and keep the particles from being disseminated about the room.

Dr. E. L. COCKS said that a patient of his had gone under the Koch treatment for lupus vulgaris. The growth had been reduced in size, but the bacilli could still be scraped off and

demonstrated under the microscope. The case was now in as bad a state as before the treatment.

The PRESIDENT said that he also had had a patient who had a very severe lupus of the face and who had taken the Koch treatment and had died the next day.

Dr. MAYER said that a case recently under his treatment would further illustrate the value of microscopic examination of sputum in doubtful cases. A man, aged forty-four years, of previous good health, was rather pale and not rugged. He had been treated for naso-pharyngitis. Examination had revealed a small cheesy mass in the tonsillar region, beneath which was a raw ulcerated surface. It had been considered to be either a case of syphilis or one of lupus. Antisyphilitic treatment had been employed, but to no purpose, as the ulcerated condition had spread rapidly. Various physicians who had also seen the case had likewise suspected syphilis, but no history of that disease could be obtained, either past or present. Now for the first time the sputum was examined and the bacilli were found in large numbers. The patient had died three months later with general tuberculosis.

Dr. M. EINHORN remarked that in manipulating sputum for examination it was advisable to heat the mass and pour off the liquid which would rise to the top. The solid material would sink to the bottom and would contain the bacilli. We little realized the virulence and extreme vitality of this bacillus. Successful inoculation had been practiced on rabbits after keeping the bacillus eight years.

Dr. HEIMAN said that it had been found to be a fact that a large number of patients had been attacked with tubercular meningitis a short time after the extirpation of tubercular glands.

The method of preparing the specimen for examination was so rapid and simple that it could be done in a few minutes, almost while the patient was dressing after a physical examination. It had been stated that ten per cent. of the internes of the large hospitals died of phthisis a short time after leaving them.

---

## Book Notices.

---

*A Practical Treatise on the Diseases of Women.* By T. GAILLARD THOMAS, M. D., LL. D., Professor Emeritus of Diseases of Women in the College of Physicians and Surgeons, New York; Consulting Surgeon to the New York State Woman's Hospital, etc. Sixth Edition, enlarged and thoroughly revised by PAUL F. MUNDÉ, M. D., Professor of Gynecology at the New York Polyclinic and at Dartmouth College; Gynecologist to Mount Sinai Hospital, etc. Containing Three Hundred and Forty-seven Engravings on Wood. Philadelphia: Lea Brothers & Co., 1891.

WHEN the popularity of Dr. Thomas's book is recalled, and it is remembered that it has been translated into all the continental and into some Oriental languages, it seems strange that since 1880 no new edition of it should have appeared. Clinical teachers become, through their writings and instruction, to a large extent the molders of professional opinion in the branches of medicine to which they devote themselves. Especially is this true in the department of gynecology, where repeated clinical observation becomes the source of knowledge. The readers of medical literature will therefore appreciate the reappearance, in handsome form, of Dr. Thomas's book, revised by so careful an observer and so facile a writer as Dr. Mundé. In his preface Dr. Mundé states that it was at the request of the author of the book that he undertook the revision, not without misgivings, as the task involved a labor equal to the writing of an original

book; and because he might find it impossible to subordinate his views to those of Dr. Thomas. The latter difficulty has been obviated in the text by placing the initials of either writer in brackets where individual opinions clash. Considering the delicacy of his task, Dr. Mundé can felicitate himself upon his achievement. Indeed, so thorough is his revision and so numerous are his interpolations that the book might almost be called his own.

It is impossible in so short a space to review the work according to its deserts. Only the most important points can be touched upon. Dr. Mundé has brought the description and classification of gynecological diseases up to the most approved pathology of the day, and the treatment advocated is of the same standard. For instance, a new chapter is included in the book on electricity as a therapeutic agent in gynecology, in which a middle ground is taken by the writer. He advocates the use of the galvanic or faradaic current in some cases, but seems to prefer the knife where electricity is sometimes indicated. The chapter on congenital malformations has been rewritten and much new and valuable material added. Dr. Thomas's belief that the perineal body represents "the inverted keystone of an arch" is corrected in this edition. New operations are described for the repair of the lacerated perinæum, for cystocele, and for proctocele. The use of pessaries is recommended with the same fervor as in previous editions, the author and reviser holding a middle ground here again. In the discussion of uterine displacements, however, the reader familiar with Dr. Thomas's former works will find marked changes. Dr. Mundé says, for example, in opposition to the views of the author: "At the present day ante flexion is generally considered to be, in its minor stages, a physiological (even congenital) condition, only productive of evil under accidental complications, and retro flexion is usually looked upon as a sequel to or companion of retroversion, and of no special consequence in itself." Dr. Mundé, in the discussion following, attributes the pathological effects of displaced uteri to backward displacements rather than to forward displacements. This is a different view from the one Dr. Thomas takes, as is Dr. Mundé's belief that retro flexions, apart from retroversions, have no distinct pathological and clinical aspects.

Much original work has been expended upon the diseases of the ovaries, and newly recognized diseases have been included. The last chapter in the book is entirely new and is devoted to the discussion of diseases of the mammæ. A new form of dressing after the operation for mastitis—the "sponge dressing," not generally known—is described at length.

Typographically, the book presents a fine appearance; most of the cuts are new and well executed. The work is an important addition to American medical literature, and will prove indispensable to the student and physician.

*Deafness and Discharge from the Ear.* The Modern Treatment for the Radical Cure of Deafness, Otorrhœa, Noises in the Head, Vertigo, and Distress in the Ear. By SAMUEL SEXTON, M. D., assisted by ALEXANDER DUANE, M. D. New York: J. H. Vail & Co., 1891. Pp. 12-13 to 89.

This little volume, which has afforded us so much gratification in its perusal, is practically an embodiment of the author's well-known papers on the excision of the drum-head and ossicles which have appeared from time to time in different medical periodicals. It presents what has long been a necessity—namely, a practical, concise, and careful review of the work done in this direction of modern aural surgery. A short sketch of surgical attempts for the relief of deafness from the earliest times is given, and our attention is called to the success of mod-

ern operators in this line in Germany and America, as regards both the permanency of the benefit secured and the satisfactory character of the immediate effects themselves. Failure in the final result among operators in former times was largely due to regeneration of the drum-head, owing to which the good effects following their operative procedures usually disappeared. The operation devised and performed by Sexton is more successful than those formerly practiced, since regeneration of the drum-head is, as a rule, completely prevented. Should this take place, a secondary operation is readily performed, resulting almost invariably in complete success. In most cases, however, there seems to be very little or no tendency to regeneration. Attention is called to the great importance of avoiding every manipulation tending to injure or irritate the drum, both during the operation and afterward, and neglect of this undoubtedly caused many of the failures in former operative procedures. Dr. Sexton's operation for the removal of the drum-head and ossicles is now more or less well known in its details and needs not to be reviewed here. If conducted with care and skill, the operation yields highly satisfactory results, and offers to the patient in its performance very little that is formidable. A rest of a day or so will see him again able to attend to his daily occupation. For the surgeon, however, the operation is one which makes considerable demands on his skill, steadiness, and knowledge—reasons enough, we presume, why it has obtained but little currency even among otologists.

The operation is held to be indicated in all cases of chronic catarrhal otitis media which display a progressive tendency and in which the subjective symptoms are referable mainly to the obstruction existing in the middle ear, and not to any marked implication of the labyrinth. Since the longer the disease is allowed to run its course, the greater the damage resulting to the parts, the obvious deduction is that the operation should be done as early as possible.

A number of instructive histories of cases are given as examples of the gratifying results of this operation in chronic catarrh and chronic purulency of the middle ear, a perusal of which will be found of great interest. Great emphasis is laid on one point in connection with the after-treatment—namely, that one should *refrain from all meddling interference with the ear*. Simple cleansing of the parts when necessary is all that is advisable. The volume closes with a short summary and general outline of the author's conclusions in regard to the operation.

*Human Monstrosities.* By BARTON COOKE HURST, M. D., Professor of Obstetrics in the University of Pennsylvania, and GEORGE A. PIERSON, M. D., Professor of Histology and Embryology in the University of Pennsylvania. Part I. Illustrated with Seven Photographic Reproductions and Eighteen Woodcuts. Philadelphia: Lea Brothers & Co., 1891.

As the authors state, there is no English work on teratology that is comparable to those of Geoffroy Saint-Hilaire, of Förster, or of Ahlfeld, and, as those works are comparatively rare and inaccessible, aside from the disadvantage of an alien tongue, there is every reason to believe that these volumes will find an audience more extensive than one composed of anatomists and embryologists solely.

It seems to us that the authors have been wise in accepting in general the classification and nomenclature employed by Saint-Hilaire, thus avoiding the further confusion that would arise from yielding to the temptation to originate a new classification and introduce new and not necessarily better terms. Klebs's classification of hermaphrodites and Förster's classification of double autositic monsters are substituted for Saint-Hilaire's.

The production of malformations is by variations in growth, by defective union, by fission, or by artificial means. Regarding the first cause, the authors believe that arrested development has its origin in a more deeply seated cause than merely mechanical apposition; the insufficient primary growth in the second cause seems also due to some deeply seated central cause profoundly influencing development; so with fission, a local cause is insufficient to explain the variation; while experiment has shown that "violent agitation, marked variations in temperature, and disturbance of the normal respiratory interchange, are all forces which, when acting on the early embryonic trace, are capable of producing profound alterations in the developmental processes."

The evident care that has been bestowed upon the preparation and production of this work foreshadows a second part of no less interest, and it is to be hoped that the authors will receive the professional support that they will undoubtedly deserve.

*The Surgical Treatment of Wounds and Obstruction of the Intestines.* By EDWARD MARTIN, M. D., Instructor in Operative Surgery, University of Pennsylvania, etc., and H. A. HARE, M. D., Professor of Therapeutics, Jefferson Medical College. Philadelphia: W. B. Saunders, 1891. [Fiske Prize Fund Dissertation, No. xl. Price, \$2.]

This essay was awarded the Fiske Prize of the Rhode Island Medical Society in 1890, and the authors state that their conclusions are based upon the results of two years' original research in the laboratory. The various chapters treat of congenital malformations; intussusception; internal strangulation; volvulus; obstruction from foreign bodies; intestinal paralysis; chronic obstruction; peritonitis; the diagnosis and general, special, and surgical treatment of obstruction; and wounds and rupture of the intestines.

The special treatment of intestinal obstruction is very carefully worked out, the authors urging rectal feeding only with whisky, beef peptoids, eggs and milk, and hot water to relieve the thirst, hypodermic injections of morphine and atropine to relieve the pain, and gastric lavage to remove all decomposing substances in the stomach. On account of the patulous condition of the pylorus, if the water used for lavage has boric or salicylic acid added, intestinal antiseptics may be furthered. They advocate injections of warm saline solutions at a pressure of two to eight pounds in obstruction, though urging great caution on account of the number of ruptures that have been reported as resulting from the employment of this procedure. In paralytic obstruction they have had good results from a powerful faradaic current. Gaseous or aerial insufflation they believe to be secondary in value to the use of warm water.

One very important feature they urge that is too often ignored, not only by writers of text-books on abdominal surgery, but by the surgeons themselves, is the preservation of heat during operations. Referring first to Brunton's and their own experiments showing that lethal doses of chloral are not fatal if the bodily heat is kept up, and to a number of thermometric observations taken in the axilla and in the rectum of patients before and after anesthesia, showing an average fall of temperature of 2.5° F., they urge that hot-water cans be placed about the patient during the operation, or, better, that he be placed on a hot-water bath.

They have made further experiments, showing that the water should have a temperature, both in the water bath and in enemata, of from 105° to 108°, as a higher temperature may produce heat dyspnoea.

The surgical treatment of these intestinal disorders and wounds is carefully considered; and the table of cases of cœli-

otomy for gunshot wounds of the abdomen is the most complete one with which we are acquainted.

The book will prove very valuable to any one interested in this branch of surgery, and the authors are to be complimented upon the conciseness with which they have treated their theme.

*A Manual of Venereal Diseases.* Being an Epitome of the most Approved Treatment. By EVERETT M. CULVER, A. M., M. D., Pathologist and Assistant Surgeon, Manhattan Hospital, of New York City, Member of the American Association of Andrology and Syphilology, and late of the Department of Venereal Diseases of the Vanderbilt Clinic; and JAMES R. HAYDEN, M. D., Lecturer on Venereal Diseases, University of Vermont, Chief of Clinic, Venereal Department of Vanderbilt Clinic, College of Physicians and Surgeons, New York. With Illustrations. Philadelphia: Lea Brothers & Co., 1891.

In this little volume the authors have attempted to give the student and practitioner an epitome of our knowledge of the venereal diseases. They have succeeded admirably. The book contains nothing foreign to the subjects to be treated, and abounds in hints and suggestions of practical value. From their opportunities of observation the authors have had a wide range of experience, and that they have cultivated these opportunities a perusal of their work will testify. It is not too much to say that the book is one of the best of the manuals of its kind for the busy physician and for the student who has not the time to go more deeply into the subject.

*On the Pathology and Treatment of Glaucoma,* being a Revised Publication, with Additions, of the Erasmus Wilson Lectures, delivered at the Royal College of Surgeons of England in March, 1889. By PRIESTLY SMITH, Ophthalmic Surgeon and Clinical Lecturer on Diseases of the Eye, Queen's Hospital, Birmingham. With Sixty-four Illustrations by the Author, and Twelve Photo-zincographs. London: J. & A. Churchill, 1891. Pp. xi-198.

SINCE the lectures of which this volume is a revised publication were delivered, in 1889, several parts of the subject of glaucoma have been more fully worked out, and the results obtained have been incorporated with the original text. The additions have chiefly been with regard to the causes of glaucomatous complications after operations for cataract, the connection between primary glaucoma and certain dimensional variations in the eye, the condition of the vortex veins in glaucoma, a description of the secondary changes produced by high pressure in the eye, and a more complete consideration of the treatment. The work now furnishes us with a very valuable compendium of what is at present known with regard to this disease.

*Quain's Elements of Anatomy.* Edited by EDWARD ALBERT SCHÄFER, F. R. S., Professor of Physiology and Histology in University College, London, and GEORGE DANCER THANE, Professor of Anatomy in University College, London. In Three Volumes. Vol. I. Part ii. General Anatomy or Histology, by Professor Schäfer. Illustrated by nearly 500 Engravings, many of which are Colored. Tenth Edition. London: Longmans, Green, & Co., 1891.

QUAIN'S *Anatomy* does not need any introduction to the medical fraternity of this country. It has been considered one of our most reliable as well as most popular text-books for many years, and there are few among us who will not welcome it as an old and tried friend.

The subdivision of each volume of this edition into parts commends itself as making the work less cumbersome and mor-

easy of access. The part at present before us gives a more thorough exposition of histology than was given in the previous editions. It is written clearly and pleasantly, and forms by itself a really valuable work on this subject. It is profusely and well illustrated and creditably got up.

*A Text-book of Physiology.* By M. FOSTER, M. A., M. D., LL. D., F. R. S., Professor of Physiology in the University of Cambridge, etc. Fourth American, from the Fifth English Edition, thoroughly revised, with Notes, Additions, and Two Hundred and Eighty-two Illustrations. Philadelphia: Lea Brothers & Co., 1891.

THE fact that since this edition has been going through the American press a sixth English edition has been published sufficiently attests the deservedly high reputation enjoyed by this work.

In the present volume the author has added some histological data in order that they may be fresh in the student's mind in entering upon the consideration of physiological questions; and he has incorporated into the text those discoveries in physiology that have been made since his former revision.

The work is fully abreast of the times, and will continue to hold the position that it has won.

#### BOOKS, ETC., RECEIVED.

*Treatise on Gynæcology, Medical and Surgical.* By S. Pozzi, M. D., Professeur agrégé à la Faculté de médecine, etc. Translated from the French Edition under the Supervision of and with Additions by Brooks H. Wells, M. D., Lecturer on Gynæcology at the New York Polyclinic, etc. Vol. I. With Three Hundred and Five Wood Engravings and Six Full-page Plates in Color. New York: William Wood & Co., 1891. Pp. xxii-581.

*Physical Diagnosis: a Guide to Methods of Clinical Investigation.* By G. A. Gibson, M. D., D. Sc., F. R. C. P. Ed., Lecturer on the Principles and Practice of Medicine in the Edinburgh Medical School, and William Russell, M. D., F. R. C. P. Ed., Pathologist to the Royal Infirmary of Edinburgh. With One Hundred and One Illustrations. New York: D. Appleton & Co., 1891. Pp. xiii-376. [Price, \$2.50.] [The Students' Series.]

*Botany: a Concise Manual for Students of Medicine and Science.* By Alex. Johnstone, F. G. S., Lecturer on Botany, School of Medicine, Edinburgh. With One Hundred and Sixty-four Illustrations and a Series of Floral Diagrams. New York: D. Appleton & Co., 1891. Pp. xiv-260. [Price, \$1.75.] [The Students' Series.]

*Surgical Anatomy for Students.* By A. Marmaduke Shield, M. B. (Cantab.), F. R. C. S., Senior Assistant Surgeon, Aural Surgeon, and Teacher of Operative Surgery, Charing Cross Hospital. New York: D. Appleton & Co., 1891. Pp. x-226. [Price, \$1.75.] [The Students' Series.]

*Tubercular Peritonitis.* By A. Vander Veer, M. D., Albany, N. Y. [Reprinted from the *Virginia Medical Monthly*.]

*Report of a Case of Hæmatophilia, or a Family of Bleeders.* By A. Vander Veer, M. D., Albany, N. Y. [Reprinted from the *Archives of Pediatrics*.]

*Report of Cases of Cholecystotomy, with Special Reference to the Treatment of Calculus lodging in the Common Duct.* By A. Vander Veer, M. D., Albany, N. Y. [Reprinted from the *Transactions of the Association of American Obstetricians and Gynecologists*.]

*Concealed Pregnancy: its Relation to Abdominal Surgery.* By A. Vander Veer, M. D., Albany, N. Y. [Reprinted from the *American Journal of Obstetrics and Diseases of Women and Children*.]

*Retro-peritoneal Tumors: their Anatomical Relations, Pathology, Diagnosis, and Treatment. With a Report of Cases.* By A. Vander Veer, M. D., Albany, N. Y. [Reprinted from the *American Journal of the Medical Sciences*.]

*Deafness and Discharge from the Ear. The Modern Treatment for the Radical Cure of Deafness, Otorrhœa, Noises in the Head, Vertigo,*

*and Distress in the Ear.* By Samuel Sexton, M. D., assisted by Alexander Duane, M. D. New York: J. H. Vail & Company, 1891. Pp. 12-13 to 89.

*Sixteenth Year Book, containing the Annual Report of the Board of Managers of the New York State Reformatory at Elmira.* For the Year ending September 30, 1891.

*The Hydratic Treatment of Typhoid Fever according to Brand, Tripiet and Bouveret, and Vogl.* By Chr. Siler, M. D., Ph. D., Professor of Histology in the Medical Department of the Western Reserve University, Cleveland, Ohio. Published by Chr. Siler. Pp. 340.

*A Practical Résumé of Modern Methods employed in the Treatment of Chronic Articular Osteitis of the Hip.* By Charles F. Stillman, M. Sc., M. D., Chicago. Detroit: George S. Davis, 1891. Pp. 118. [*The Physicians' Leisure Library*.]

*The Improvement of Evacuators for Litholapaxy and the Later Developments of the Operation.* By Otis K. Newell, M. D., Boston. [Reprinted from the *Medical Record*.]

*The Treatment of Urethral Stricture, and a New Divulsor for Rapid Dilatation.* By Otis K. Newell, M. D., Boston. [Reprinted from the *Medical Record*.]

*How should we proceed when Abdominal Tumors are complicated by Pregnancy?* By James F. W. Ross, M. D., L. R. C. P. Eug. Toronto, Canada. [Reprinted from the *Transactions of the American Association of Obstetricians and Gynecologists*.]

*Clinical Aspects and Ætiological Relations of Cutaneous Tuberculosis.* By James C. White, M. D., Boston. [Reprinted from the *Boston Medical and Surgical Journal*.]

*A Hint to the Literary Men of the Profession.* By Charles Perry Fisher. [Reprinted from the *Medical News*.]

*The Application of Sacral Resection to Gynæcological Work.* By E. E. Montgomery, M. D., Philadelphia. [Reprinted from the *Transactions of the American Association of Obstetricians and Gynecologists*.]

*Criminal Aristocracy, or the Mafia.* By Arthur MacDonald, Worcester, Mass. [Reprinted from the *Medico-legal Journal*.]

*On the Ferments contained in the Juice of the Pineapple (*Ananassa sativa*), together with some Observations on the Composition and Proteolytic Action of the Juice.* By R. H. Chittenden, assisted by E. P. Joslyn and F. S. Meara. [Reprinted from the *Transactions of the Connecticut Academy*.]

*The Technique of Cerebral Surgery.* By G. Wiley Broome, M. D., St. Louis. [Reprinted from the *Weekly Medical Review*.]

*Report of a Case of Spina Bifida, with Partial Motor and Sensory Paralysis of both Extremities, Complete Paralysis of the Sphincters of the Bladder and Rectum, Double Equino-varus, and Purulent Bursitis.* By H. Augustus Wilson, M. D., Philadelphia. [Reprinted from the *Transactions of the American Orthopedic Association*.]

*The Aseptic Closure of Long-standing Sinuses having their Origin in Tubercular Joints.* By H. Augustus Wilson, M. D., Philadelphia. (Read before the Philadelphia Academy of Surgery, November 2, 1891.)

*Scope of Orthopædics—Forms of Club-foot Tenotomy.* By H. Augustus Wilson, M. D., Philadelphia. [Reprinted from the *Medical and Surgical Reporter*.]

*Hand Disinfection.* By Howard A. Kelly, M. D., Baltimore. [Reprinted from the *American Journal of Obstetrics and Diseases of Women and Children*.]

*The Ideal Dressing for the Abdominal Wound.* By Howard A. Kelly, M. D., Baltimore. [Reprinted from the *American Journal of Obstetrics and Diseases of Women and Children*.]

*Osteopenthesia.* By B. Merrill Ricketts, M. D., Cincinnati, Ohio. [Reprinted from the *Journal of the American Medical Association*.]

*The Surgical Treatment of Pyloric Stenosis, with a Report of Fifteen Operations for this Condition.* By N. Senn, M. D., Ph. D., Chicago. [Reprinted from the *Medical Record*.]

*A Code of Rules for the Prevention of Infectious and Contagious Diseases in Schools. Being a Series of Resolutions passed by the Medical Officers of Schools Associations. Third and Revised Edition.* London: J. & A. Churchill, 1891.

*The Middlesex Hospital. Reports of the Medical, Surgical, and Pathological Registrars for the Year 1890.* London: H. K. Lewis, 1891.

The Transactions of the Association of Military Surgeons of the National Guard of the United States, for the Year 1891. Chicago.

Report of the Health Department of the City and County of San Francisco, for the Fiscal Year ending June 30, 1891.

**On Some Painful Affections following Influenza.**—Dr. A. Ernest Sansom, F. R. C. P., Physician to the London Hospital, etc., contributes the following article to the *Lancet* for January 2d:

I propose in this short communication to pursue the inductive method of reasoning in regard to some cases which at one time caused me considerable perplexity. I will first mention a case which initiated my difficulties. A gentleman aged fifty-three, who for many months previously had been in fair average health, was taken during the night with severe pain in the right hypochondrium. The signs simulated those of hepatic colic. He took a mild aperient, and the attack passed away after one to two hours and he slept. The following day the bowels were properly opened, there was no evidence of absence of bile from the motions, the urine was in all respects normal and contained no bile or excess of coloring matter. The attacks of severe pain, however, recurred at intervals—mostly in the night, but sometimes during the day—for about ten days, treatment by opium and belladonna only relieving them. It seemed that the gall-bladder could be mapped out by the area of tenderness, but never was there the slightest jaundice. On one night there was sharp diarrhoea. I could only say that the attacks were those of hepatalgia of paroxysmal recurrence. In hunting about for a cause, the only antecedent which seemed at all probable in this direction was an attack of influenza contracted in Paris at the very earliest time of the epidemic, and followed by protracted enfeeblement. I computed that nearly twenty months must have elapsed between the original attack and these consequences, if they were consequences. There was no evidence of reinfection, but of course this was possible.

The key seemed to be furnished by a number of experiences which came to me just about the same period as this first instance. In all there was fair evidence of an attack of influenza followed at intervals, extraordinarily variable, by signs of extreme pain and distress. In twenty-four such cases the sites of pain could be thus tabulated: 1. Epigastrium, nine cases; abdomen generally, two cases; localized in hepatic area, one case. 2. Head, various sites, seven cases; supra-orbital region, one case; right inferior maxilla, one case. 3. Heart region, seven cases. 4. Extremities: hips and legs, two cases; calves, two cases; arms, two cases; right sciatic region, one case; fingers, one case; lumbar region, one case.

In Group 1 in some cases the pain at the epigastrium was nearly constant. For instance, a man aged sixty-six, who had been previously quite healthy, caught influenza at Christmas, 1890, and had never felt well since. Six months afterward he had constant pain at the epigastrium, with craving for food. Food slightly relieved the pain, but soon after nausea occurred, with pyrosis. In most cases the pain was paroxysmal, and frequently nocturnal, sometimes attended with vomiting or pyrosis. Peculiar symptoms occurred in some of these cases, as "a feeling as of a cold wind over the chest, and inability to take a deep breath." In some the signs of colic, as in the first case mentioned,

were closely simulated; frequently there was retching, but the tendency was rather to diarrhoea than to constipation. In one case, a man of sixty-three, suffering from intense epigastric pain, with sense of heavy weight preventing sleep, and some vomiting, I found a small patch of herpes zoster below the angle of the right scapula.

In Group 2 were various neuralgias. In one man aged thirty-eight there was intense supra-orbital neuralgia varying from side to side; previously there had been rigor and abdominal pain like colic, and then sweating and palpitation. He had suffered from influenza twelve months previously, but no ailment since. In another case, a lady aged twenty-five, urticaria followed influenza, and twelve months afterward attacks of vertigo, with palpitation of the heart and pain referred to the occipital regions. A lady of thirty-seven, who had suffered from an attack of influenza in May, 1891, averred that two months afterward she commenced to have headache, from which she had never been free in her waking hours for three months subsequently; she also suffered from pain on movement of the right lower jaw. She had tremors and tinnitus aurium, but no vertigo. In others headache occurred coincidentally with gastric crises.

In Group 3 some of the patients referred the pain which they suffered very closely to the region of the heart. In a few cases the pain was persistent, but in most paroxysmal. A lady aged forty-two, who had suffered from influenza nine months previously, described the pain as constant and dull, limited to the heart region. A gentleman aged thirty-six, whose attack dated sixteen months previously, was wearied with such dull aching; it was rather more diffused than in the former case. In another gentleman, aged forty-two, the constant pain in the cardiac region was accompanied by a tingling down the left arm. The most important and characteristic cases in this group, however, simulated angina pectoris. A gentleman aged thirty-one, typically athletic, who had never suffered from illness before his attack of influenza, which was very severe, was taken five months afterward with sudden and violent pain at the heart, eventuating in syncope. He was standing with his back to the fireplace talking with friends, when the attack seized him with violence, and he fell unconscious upon the hearth-rug. There was no epileptoid sign. Another attack occurred a week after. There could be no doubt from collateral evidence that the patient became faint to unconsciousness. In the intervals no notable deviation from health could be detected; the left ventricle was slightly hypertrophied, but not more so than could be expected in an athletic subject. The patient described the pain as of the character of a "grip" or "screw" at the heart; he experienced no coldness, and repudiated any sense of impending death. There were occasionally, also, some attacks of dyspnoea, occurring independently of exertion. Nearly at the same time at which this patient came under my observation a gentleman came under my care with like symptoms, in whom there was no evidence of an attack of influenza. He presented the appearance of typical good health, but suffered attacks of terrible pain at the heart, ending in complete unconsciousness. On some occasions the attacks were followed by wild excitement, and the patient had to be restrained from self-violence. I have reason to believe that in both these cases there was complete recovery. In a lady, aged forty-one, attacks of intense pain were initiated by exertion. The pain was localized in the second left intercostal space—presumably over the superior cardiac plexus—and here was a tender spot. The pulsations of the heart were painfully felt when in the recumbent position. In some other cases there was a feeling of impending death, as in true angina pectoris, though the pain was much less severe. This occurred in a gentleman aged thirty-three, sixteen months after an attack of influenza. Pain referred to the heart, however, had occurred at intervals ever since his attack. In the case of another gentleman, aged thirty-seven, the sensation was described as of an arrest of the heart, as if the pendulum of a clock had been stopped at one swing. With this the patient said: "I feel as if I were going to die." In some cases there was a manifest slowing of the pulse; in others an irregularity. Sometimes a slow alternated with a quick pulse. Fifteen months after an attack of influenza I counted the pulse of a lady aged twenty-two as fifty-six. In most cases the rate was rapid, and I do not remember one case in which the arterial tension was unduly prolonged. This absence of prolonged arterial tension, in my opinion,

took the cases out of the category of true angina pectoris. I have not heard that any case was fatal.

It is no part of my purpose to pursue the question of the cardiac phenomena of influenza. These furnish most interesting lessons, but I am concerned now only with the manifestations of *pain*. I turn now to Group 4, in which there were painful affections of the extremities. A lady aged twenty-five, who had an attack attended with high fever four months previously, complained of intense aching in both arms. This occurred chiefly at night, and she actually wept on account of the pain. Previously to the manifestation in the arms she had suffered pain in the calves of the legs, resembling that of neuritis. In another case of a gentleman, aged forty-one, the pain was referred to the lumbar regions more on the left side, to the right shoulder and the left wrist, to the course of the right sciatic nerve, and to the muscles of the thigh. There were fearful exacerbations, chiefly nocturnal, so that the patient, previously a healthy man, actually shrieked on account of the pain. In the case of a female aged thirty-three pain was localized in the muscles of the calves of the leg and of the thigh. The pain was strongly aggravated after food, especially meat. In another female, aged twenty-three, pain was extremely violent in the thighs and legs, and there were attacks of faintness. Subsequently the suffering was localized in the course of the right sciatic nerve. It was subject to remissions, with severe nocturnal exacerbations; there were also shooting pains at the epigastrium. The case was of alarming intensity, but recovered. In a lady aged forty-eight pain was referred to the right hip and to the right arm; it extended from the right shoulder to the fingers, and all movement caused pain.

There could be little doubt that in these cases there was a form of neuritis. I met with other analogous instances in which there had been no history of influenza: One case in a child in whom there was severe pain in the calves, dropped feet, absolute loss of motor power, and, in fact, all the signs of neuritis of the alcoholic form. Any causation by alcohol was in this case quite out of the question; no doubt it was due to some infectious cause, and resembled the cases of peripheral neuritis, due to no traceable contagion, recorded by DeJérine and others.

In this summary of my personal experiences I have dealt with no cases of the earliest manifestations of influenza; all were in patients whose attack had passed away and who were not confined to their homes. The periods between the attack of influenza and the manifestations of symptoms of pain varied from a few weeks to twenty months.

The evidence appears to me to confirm the view of Dr. Althaus that the *materies morbi* of influenza resembles the syphilitic virus in its tendency to attack many parts of the nervous system after the attack is over, but surpasses the syphilitic toxine in virulence and in rapidity of action. Dr. Althaus\* has adopted the deductive method in his reasoning. Starting from certain probabilities, he has worked out the problems of the effects of the *materies morbi* if it should specially attack certain areas of the central nervous system. He concludes that the different forms of influenza are due to irritant poisoning of the bulb and the nerve nuclei contained in it. Adopting a converse method, that of logical induction, and taking my arguments alone from personal experience, I have arrived at a similar conclusion to Dr. Althaus in so far as the proposition is concerned—that the virus of influenza especially affects the nervous system. Leaving the question of the acute and early manifestations, however, which I agree with Dr. Althaus in considering to be due to involvements of certain areas in the medulla oblongata, it appears to me most probable that the consequent phenomena are better to be explained by inflammatory changes in certain peripheral parts of the nervous system. In regard to the *visceral neuralgic*, the hepatalgia, the gastralgia, and cardialgia, there are signs of localization and, in some instances, of local tenderness that point to a local cause. In some such it seems probable that the sympathetic fibers and ganglia are alone affected. In other cases, as in those in which there seems to be temporary arrest of the heart's action, retching, vomiting, and various disturbances of digestion, it is most probable that the vagus is involved in greater or less degree; but here also the effects might be due to peripheral irritation. In the sensori-motor manifestations it can scarcely be possible to avoid the conclusion that

there is in existence a form of neuritis analogous to that which is caused by many other toxines. The conclusion, therefore, which I have come to is that the various affections I have briefly described are the remote consequences of the influenza infection, and that their proximate cause is a peripheral neuritis affecting the sympathetic ganglia and nerves, the vagus, and the sensori-motor nerve trunks.

**Infantile Deformities and Maternal Impressions and Emotions.**—The following presidential address before the Obstetrical Society of Glasgow, by Dr. George Halket, is published in the *Glasgow Medical Journal* for January:

There are few things more painful to a mother than to give birth to a child that is in any way deformed. How often do we hear a mother say that it matters little to her whether her child is a boy or a girl, or what it is like, or whom it is like, so long as it is "like the world."

We are apt to look upon these words as an idle tale, and worthy of little attention; but I firmly believe that they bear more real significance than they generally get credit for.

A deformed child is a lifelong sorrow to its mother, and an object of pity as long as it lives, yet we not infrequently see children come into this world deformed as to their face, their limbs, or other parts of their body, and bearing these deformities along with them from their cradle to their grave.

The deformities of which I am going to speak are those which have occurred in children at whose birth I attended, with whose family history I was acquainted, and, in the case of those who survived, whose subsequent career I have been able to follow.

I will take first those deformities affecting the head and face, then those affecting the upper extremities, then the lower extremities, and then those affecting the trunk.

The case of greatest interest affecting the face and head was the child of a woman residing in Stobcross Street. It was her second child, the first being as healthy and well-formed a boy as one could wish to see, and who is still alive. The child of which I am speaking was also a boy. Its nose was only partially developed, being very small, and had only one nostril. It had the appearance as if only half the nose were there. The right eye was situated considerably further back on the head and at a much lower level than the left eye. The child could not close that eye, and, sleeping or waking, the right eye was always wide open. On the right side of the forehead there was a small growth, half an inch in length, tipped with bone, and which looked like a small horn. This I took to be the undeveloped part of the nose. The child was otherwise strong and healthy, and lived till it was fifteen months old, when it died of acute bronchitis.

There were five cases of hare-lip. Two of these were simple and uncomplicated, and situated on the left side of the median line. These were successfully operated upon. Two cases, one on the right side and one on the left, were complicated with cleft palate. One died in infancy from bronchitis, the other was operated upon and is still alive. The fifth case was a double hare-lip, with cleft palate, and died in the Western Infirmary, whither it was taken for operation.

I had three cases of children with hydrocephalic heads, all dead-born. One of these required perforation and the application of the forceps; another, born at the end of the eighth month, was delivered with the aid of the forceps. This child had no neck, the head being fixed directly on the shoulders. The third case was a breech presentation, and was delivered with great difficulty. The bones of the head in this case were not united, otherwise craniotomy would have required to have been performed.

I had one case of complete ossification of the bones of the head. The mother of this child had had a large family, and all her confinements were normal. In the present case, after the cervix was completely dilated, the head remained for a considerable time above the brim of the pelvis. To aid delivery, I applied the forceps, but, do what I could, I made no impression on the position of the head. The case being in Crosshill, I got the assistance of Dr. Nairne, but with no better result. We then decided to turn, and again the head gave trouble. It was only after efforts which exhausted us both that the child was brought into the world, with a head as round as a ball and as hard as a stone.

\* *The Lancet*, November 14 and 21, 1891.

Coming now to the deformities affecting the upper extremities, there was one case where the forearms were only partially developed—that is, they were short and thin as compared with the upper arms, and they were firmly fixed at right angles to the upper arms, to which they were attached by a thin web-like membrane of skin and fibrous tissue. On each hand only the thumb and forefinger were present. This child was dead-born, but the mother believed it was alive at the beginning of labor.

The next case was a child born at the end of the eighth month of pregnancy. It had both hands firmly fixed at right angles to the forearms, and resembled the condition which is found in talipes equinovarus in the foot.

There was one child born in which the index and middle fingers of the left hand were not developed, and two cases where the child was born with a sixth finger on the left hand. As the attachments of these sixth fingers were only slight, I separated them and bandaged the hands.

In the lower extremities the only deformity I had was that of club-foot, and of this I had three cases—all of the talipes equino-varus type. In two of these cases only one foot was implicated; in the third, both feet.

All were successfully operated upon.

I had one case—a breech presentation—where one of the feet was very much twisted by intra-uterine pressure, and had all the appearance of a bad club-foot; but manipulation and bandaging eventually restored it to its proper shape.

On the trunk I had three cases of spina bifida. One was in the dorsal region and had no tumor. One was in the lumbar region, and the third was over the upper part of the sacrum. The first two cases died within a few days of their birth from convulsions. The third case did well, the tumor taking on a thick covering of skin. This child, a boy, is still alive, and about eight years of age. He was three years old before he could walk, still walks with a stooping and shuffling gait, and is not intellectually the equal of his brothers and sisters.

These, gentlemen, are the deformities and malformations worthy of note which have occurred in my midwifery practice, and the question now arises, Can their appearance in any way be explained?

The belief that maternal impressions and emotions affect the development of the fœtus has existed from the earliest periods, and, up to the beginning of the eighteenth century, was generally accepted by the medical profession. From that date up till now, and more especially within the last fifty years, writer after writer, and among them men of distinction, both in this country and America, have expressed their disbelief in this theory, and have written many articles to controvert it.

They hold that maternal impressions or emotions are exceedingly common among pregnant women, and that deformities are very rare.

That deformities sometimes occur when there was no history of maternal impression.

That when deformities follow well-marked maternal impressions, they are due to coincidences, and are not cause and effect.

That there is no nerve tissue in the umbilical cord, and that mental emotion can not in this way be carried from the mother to the child. And, further, that, as the action of maternal impressions and emotions can not be explained pathologically, they can have no effect whatever on the fœtus *in utero*.

But, gentlemen, "there are more things in heaven and earth than are dreamt of in our philosophy," and case after case has been put on record, substantiated and confirmed by medical men whose names are sufficient guarantee, that mental impressions and emotions do sometimes affect the development of the fœtus.

One thing is certain: that, knowing the sympathy that exists between the brain and the womb, if there is one time more than another when a woman should be treated with gentleness and care, when her surroundings should be pure and free from anything that is repulsive, it is when she is pregnant.

If, on the other hand, we see her exposed to everything that is bad—the fury of a drunken husband and the annoyance of quarreling neighbors, hearing obscene language and seeing foul sights; if, in addition to that, we find her addicted to drunkenness and the other evils

that spring from that—there is little wonder that the course of nature in the development of the fœtus should sometimes be interfered with.

Now, what do we find in the cases that I have laid before you?

In the first case, where the nose was only partially developed and where the right eye was displaced, the father of the child was at that time a confirmed drunkard and frequently assaulted his wife. There was a history of repeated kicks and blows over the abdomen during the early months of pregnancy, not discovered only after the birth of the child, but of which I was made aware at the time, and measures had to be taken on more occasions than one to prevent abortion. In this case I believe the deformities were the result of external violence.

Taking next the deformities which were due to arrest of development—hare-lip, cleft palate, and spina bifida—there was not, so far as I was made aware, in any of them any history of particular maternal impressions, but there were in every case circumstances which I believe tended to cause these deformities.

In the two worst cases of hare-lip and cleft palate the mothers were given to frequent and long-continued fits of intemperance; and from this cause, aggravated by violent emotions, to which every intemperate person is exposed, the blood became vitiated and so changed as to interfere with the proper nutrition and development of the child.

In two other cases the mother suffered bereavement about the time of conception, and had long periods of grief and mental depression. Another was deserted by her husband and left in poverty and suspense, and the others suffered in many ways from ill treatment and neglect.

Now, bearing in mind the absolute dependence of the fœtus on the blood of the mother, it is not difficult to imagine how mental emotion, long continued, should so affect the quality of the maternal blood as to cause it to act injuriously on the child.

In the two cases where the hands and arms were deformed or only partially developed I did not seek for any history of maternal impression. I thought it better in each case that the mother should be kept in ignorance of the deformity of her dead child.

But there was one case that would not hide, and that was where the child was born alive with the index and middle fingers wanting from one of its hands. The mother was a young woman who knew nothing about maternal impressions, but, when she was made aware of the state of her child's hand, she stated without hesitation that she had to work for some months after her marriage, that the foreman under whom she worked had lost two fingers through an accident, that when she saw his hand for the first time she had a "grueing," or shivering, and that every time she saw him she could not keep from thinking of his deformed hand.

A few years ago an interesting correspondence was carried on in the *British Medical Journal* on the subject of maternal impressions, and medical men in different parts of the country gave an account of cases which had come under their own observation. One medical man had a patient who, in the early months of her pregnancy, wished to have her ears repierced, that she might wear her ear-rings again. When she got this done she wished she hadn't, and the matter preyed heavily on her mind. When she was confined, it was found that the child's ears were likewise pierced, and a thread was passed through one of them.

Another related how a patient of his, in her first pregnancy, was served daily with milk by a boy who had lost his middle finger, and that as he handed her the milk she always observed the absence of that finger. When her child was born, the middle finger of one of its hands was wanting.

A third medical man described how a workman was brought into his surgery with one of his hands cut right off by some machinery. He narrated this incident to a lady friend of his, who was at that time in the early months of pregnancy, on whose mind it made a marked impression, and who could not keep from detailing the incident to others. Her child was born with only one hand.

Another doctor had a patient who, about the time of her conception, had lost a near and dear relative. Her grief was inconsolable, and she spent the early months of her pregnancy in weeping and covering her

eyes with her handkerchief. When her child was born it was born blind.

And this brings me to speak of a case that occurred in my own practice, now a good many years ago, but the facts of the case are as firmly impressed on my mind as if they had occurred only yesterday. It was the saddest case I ever had, for though the confinement was as simple a one as I ever attended, the child was born dead, and the mother died within a few hours afterward, and that from no apparent cause.

On October 4, 1884, a lady residing in the western district of Glasgow called upon me and asked me to attend her in her confinement, which she expected about the middle of December. It was to be her third confinement. Both previous confinements had been normal, and I had attended her in her second confinement, when she made a good recovery. I remember telling her that I did not think she looked quite as well as she did when I saw her last, and she replied that since the death of her mother, who had resided with her, she had felt dull and lonely, and was often in low spirits. Otherwise, she said, she was in good health.

I may here mention that, though I had been frequently in her house visiting her mother and her children, I had never been asked to prescribe for herself, and none of her friends ever suspected her to be suffering from any bodily trouble.

I did not see her again till the early morning of December 9th, when I was called to her confinement. I found her sitting at the kitchen fire, the very image of despair. On my advice she went to bed, and on examination I found the labor well advanced, the head presenting normally, and the membranes unruptured. The pains were strong and regular, and with every pain she cried out in a tone which resembled that of grief rather than of bodily suffering: "Oh, my poor mother, my poor mother." I told her that she was not bearing up so well as she did at her previous confinement, and encouraged her as well as I could. She paid no attention to what I said, but with every pain kept crying: "Oh, my poor mother, my poor mother." Shortly afterward the membranes ruptured, and in a few minutes the child came into the world, but the first view I got of it convinced me that it was dead. There was no discoloration of any part of its body, but it had that soft, white appearance which indicated the absence of life. I did attempt resuscitation, and while doing so asked her when she found the movements of the child last, and she answered that she had felt no "life" since her mother died. Now, her mother had been dead nearly a year.

After removing the placenta and bandaging her, I waited a short time to see that the uterus was contracting properly, and then left her, to all appearances well. In about three hours afterward I was called hurriedly to come back and see her, and was just in time to see her breathe her last. There had been no undue hemorrhage, internal or external; and the only information I could get was that she had attempted to sit up, and had fallen back in a fainting fit.

I was visiting in the neighborhood the following day, and reference was made to what had happened. I stated that I had difficulty in accounting for the cause of death, but the lady to whom I was speaking said she believed the cause of death was a broken heart. And then she told me how in the summer time she had frequently met the deceased lady at the coast, and how her whole talk on every occasion was about her dead mother.

Gentlemen, I have laid before you, for your opinion, every fact of this sad case with which I am acquainted; but whatever the scientific or pathological explanation may be, I am firmly convinced, in my own mind, that the death of this child and the death of its mother are in some way connected with maternal emotions.

**The Function of the Peroneus Tertius Muscle.**—Mr. W. Ramsay Smith, B. Sc., Demonstrator of Anatomy, Edinburgh School of Medicine, contributes the following to the January number of the *Edinburgh Medical Journal*: Recently, in the course of studying the actions of the muscles of the lower extremity with the view of determining what muscular movements take place in walking, I was fortunate to meet with some clinical cases worth recording. In this note I shall confine my remarks to two cases illustrating the function of one muscle—the *peroneus tertius*.

The first case was one in which the *peroneus tertius* of the left side was subjected to a continued strain by the patient sitting for an hour or two in a cramped position, with the heel on the ground, the ankle joint fully extended, and the toes turned in. When the patient, in the act of walking, placed the heel on the ground and allowed the weight of the body to fall on the advanced leg, the sole of the foot came down all at once with a *flap—flap*, and pain was felt at each step taken with this foot. The pain was referred to a spot corresponding to the origin of the *peroneus tertius* muscle. The patient found it impossible to stand on the heel of the left foot; every attempt to do so resulted in the sole of the foot coming down *flap* on the ground, and was accompanied by intense pain in the part of the leg I have referred to. On carefully testing the condition of the *extensor longus digitorum*, *extensor proprius hallucis*, and *tibialis anticus* muscles, I could discover no abnormality; the power of these muscles to resist flexion of the toes and extension of the ankle was as great as usual, and no pain was elicited by such testing. This condition of paralysis continued for about three days, when the muscle gradually regained its power. During that time walking was practiced by keeping the knee slightly more bent than usual, turning the toes slightly more outward, and placing the sole of the foot on the ground at each step of the left foot. In this way there was no pain accompanying the act of walking, and the difference of gait was scarcely perceptible.

The second case was one in which the patient, on descending from a high leap, alighted on the ground on his right heel, the ankle being at the time extended. The symptoms in this case were similar to those in the former, only they were more aggravated; and examination showed that the *extensor longus digitorum*, particularly the outer part of it, was also involved in the strain. The power of this extensor to resist flexion of the toes was impaired, and the pain in the leg was correspondingly increased in its distribution. The act of walking was performed as in the former case.

These two cases illustrate very clearly the action of the *peroneus tertius* as a muscle of ordinary walking when the heel is the first part of the foot to touch the ground. Acting with the *tibialis anticus*, and aided by the extensors of the great and other toes, it prevents the foot from coming forcibly down on the ground, which it tends to do, as soon as the weight of the body bears on the ankle joint; in other words, these muscles on the front of the leg prevent "spasmodic" extension of the ankle joint in ordinary walking. The action of this muscle, too, in helping to maintain the erect posture of the body becomes apparent; and this action goes very far to explain, if it does not make perfectly clear, how the *peroneus tertius* muscle is the peculiar property of the human subject, no other mammal possessing it.

I have not yet seen an instance of the absence of this muscle, and I am unable to say what the state of matters may be in such instances; but it would be instructive to know the condition of the *extensor longus digitorum* to the little toe, and whether any peculiarity exhibited itself in the gait of persons in whom the *peroneus tertius* was absent.

**A Physician's Estimate of his Class.**—In Dr. S. Weir Mitchell's interesting "medicated novel," *Characteristics*, that is being published in the *Century*, there is the following description of varieties of medical men that will suggest acquaintances to many of our readers: "There is no place where good breeding has so sweet a chance as at the bedside. There are many substitutes, but the sick man is a shrewd detective, and soon or late gets at the true man inside of the doctor.

"I know, alas! of men who possess cheap manufactured manners adapted, as they believe, to the wants of 'the sick-room'—a term I loathe. According to the man and his temperament do these manners vary, and represent sympathetic cheerfulness or sympathetic gloom. They have, I know, their successes and their commercial value, and may be of such skillful make as to deceive for a time even clever women, which is saying a great deal for the manufacturer. Then comes the rarer man who is naturally tender in his contact with the sick, and who is by good fortune full of educated tact. He has the dramatic quality of instinctive sympathy, and, above all, knows how to control it. If he has directness of character too, although he may make mis-

takes (as who does not?), he will be, on the whole, the best adviser for the sick, and the completeness of his values will depend upon mental qualities which he may or may not possess in large amount.

"But over and above all this there is, as I have urged, some mystery in the way in which certain men refresh the patient with their presence. I fancy that every doctor who has this power—and sooner or later he is sure to know that he has it—also learns that there are days when he has it not. It is in part a question of his own physical state; at times the virtue has gone out of him.

"I had a rather grim but most able surgeon. He seemed to me to have a death-certificate ready in his pocket. He came, asked questions, examined me as if I were a machine, and was too absorbed in the *physical me* to think about that *other me* whose tentacula he knocked about without mercy, or without knowledge that tenderness was needed. Our consultant was a physician with acquired manners. He always agreed with what I said, and was what I call aggressively gentle; so that he seemed to me to be ever saying with calm self-approval, 'See how gentle I am.' I am told that with women he was delightfully positive, and I think this may have been true, but he was incapable of being firm with the obstinate. His formulas distressed me, and were many. He was apt to say as he entered my room, 'Well, and how are we to-day?' And this I hated, because I once knew a sorrow undertaker who, in the same fashion, used to associate himself with the corpse, and comfort the living with the phrase, 'We are looking quite natural to-day.'"

**The New York Academy of Medicine.**—At the next meeting of the Section in Laryngology and Rhinology, on Wednesday evening, the 27th inst., Dr. H. Hoyle Butts will read a paper entitled A Comparison of some Recent Methods for removing Adenoids from the Vault of the Pharynx.

At the next meeting of the Section in Obstetrics and Gynecology, on Thursday evening, the 28th inst., Dr. Robert L. Dickinson will read a paper on The Diagnosis of Pregnancy between the Second and Eighth Weeks by Bimanual Examination, and Dr. Victoria M. Davis will read a paper on The Preventive Treatment of Mastitis.

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. Walter Wyman, Surgeon-General of the Marine-Hospital Service, and published in the Abstract of Sanitary Reports for January 15th:

CITIES.	Week ending—	Population, U. S. Census of 1890.	DEATHS FROM—											
			Total deaths from all causes.	Phthisis pulmonalis.	Yellow fever.	Small-pox.	Variceloid.	Varicella.	Typhus fever.	Energetic fever.	Scarlet fever.	Diphtheria.	Measles.	Whooping-cough.

**The Pan-American Medical Congress.**—The committee on organization of the Pan-American Medical Congress, at its meeting at St. Louis

last October, elected the following international executive committee: *The Argentine Republic*, Dr. Pedro Lagleyze, Buenos Aires; *Bolivia*, Dr. Emelio Di Tomassi, La Paz; *Brazil*, Dr. Carlos Costa, Rio de Janeiro; *British North America*, Dr. James F. W. Ross, Toronto; *British West Indies*, Dr. James A. De Wolf, Port of Spain; *Chile*, Dr. Moises Amaral, Santiago; *United States of Colombia*, Dr. P. M. Ibañez, Bogotá; *Costa Rica*, Dr. Daniel Nuñez, San José; *Ecuador*, Dr. Ricardo Cuelon, Guayaquil; *Guatemala*, Dr. José Monteris, Guatemala Nueva; *Haiti*, Dr. D. Lamothe, Port au Prince; *Spanish Honduras*, Dr. George Bernhardt, Tegucigalpa; *Mexico*, Dr. Tomás Noriega, City of Mexico; *Nicaragua*, Dr. J. I. Urtecho, Grenada; *Peru*, Dr. J. Casamira Ulloa, Lima; *Salvador*, Dr. David J. Guzmán, San Salvador; *Spanish West Indies*, Dr. Juan Santos Fernandez, Habana; *United States*, Dr. A. Vander Veer, Albany, N. Y.; *Uruguay*, Dr. Jacinto De Leon, Montevideo; *Venezuela*, Dr. Elias Rodriguez, Caracas. Hawaii, Paraguay, Santo Domingo, the Danish, Dutch, and French West Indies are not yet organized. Nominations of local officers have been received from a majority of all the members of the international executive committee, and a number of the lists have been confirmed by the committee on organization. These will be announced as rapidly as acceptances are received.

**To Contributors and Correspondents.**—The attention of all who purpose favoring us with communications is respectfully called to the following:

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Original Communications.

THE PROGRESS OF CYSTOSCOPY  
IN THE LAST THREE YEARS.\*

By WILLY MEYER, M. D.,

ATTENDING SURGEON TO  
THE GERMAN AND NEW YORK SKIN AND CANCER HOSPITALS.

THREE years ago Dr. Max Nitze, of Berlin, the inventor of the cystoscope, in his well-known essay, Contribution to Endoscopy of the Male Bladder,† stated that we could now, with the help of the cystoscope in its handy and improved shape, establish a strict differential diagnosis between the diseases of the bladder. He further said: "Having seen with the cystoscope that the bladder is healthy, and that the morbid process therefore involves the upper urinary passages, most probably the kidneys, it is tempting to put the question whether we shall be able to prove with the cystoscope which kidney or which pelvis of the kidney is diseased. Either we could attempt to push a thin catheter under the guide of our eyes into the orifice of the ureters, to draw the urine directly from each kidney separately, or we might be able to observe with the cystoscope out of which ureter the blood escaped in a case of hæmaturia," or, I may add, pus or purulent urine in a case of pyelitis or suppurating kidney.

It was obvious from the beginning that Nitze's statement would be sustained by all who practiced cystoscopy—namely, that our knowledge as well as the diagnosis of bladder diseases would just as rapidly widen, clear up, and improve with the help of the new cystoscope as our knowledge of laryngeal diseases, for instance, did after the invention and introduction of the laryngoscope. But would Nitze's hope also be realized, or could it be realized, in regard to kidney troubles? Might we hope to be able to use his cystoscope as at least one means of observing the "character" of the urine in its direct descent from each kidney?

Reviewing the literature on cystoscopy which has appeared since 1887, and the results of my own work in this line, covering now (December, 1891) a period of nearly four years, we can unhesitatingly answer this question in the affirmative.

Before treating of the progress in the diagnosis and treatment of "kidney" diseases with the help of the cystoscope—the special object of my paper—any further, I will try to give a short review of the development of cystoscopy in general, with reference to the construction of additional instruments, made in accordance with the principles laid down by Nitze, and to its influence upon the diagnosis, prognosis, and treatment of diseases of the bladder.

I. INSTRUMENTS.

After three years' careful trial and comparison of the two chief cystoscopes which have been in the market—viz., that of Dr. Max Nitze, manufactured by Paul Hartwig, of

Berlin (*Markgrafenstrasse*, 79), and that of Mr. Joseph Leiter, the well-known instrument-maker of Vienna, manufactured by himself (*Mariannengasse*, 11)—I must slightly alter my remark, made a few years ago,\* that I "prefer" Nitze's instrument. It is true, I still mostly use it, because I have become accustomed to it, and because it seems to me that the picture, as seen through its prism and lenses, is more stereoscopic.† I also believe that, in order to avoid diagnostic errors, it is better to train one's eyes exclusively on one instrument. After experience has been acquired, it is immaterial which instrument is used. And since Leiter has slightly altered the pattern of his instrument in accordance with the suggestion of Harry Fenwick, of London, he has secured the essential advantages of Nitze's cystoscope and eliminated the former disadvantages of his own. Leiter's instrument is now most highly finished and perfectly reliable.‡ "The length of the beak is reduced to less than an inch.# The elbow is well rounded; the length of the shaft is seven inches and a half. The ocular end is fitted with a rotatory plate, carrying the binding screws, while, instead of the Nitze slot-key, a small screw upon the face of the plate forms a more convenient switch."|| In the Leiter instrument of 1887 the beak was nearly half an inch longer, the elbow presented an angle, the shaft was too short, and the battery wires had to be fastened in the binding screws, which were immovable upon the instrument, and thus would twist around it, if the latter was turned around its longitudinal axis in the bladder. The only difference, then, which still exists between the two German instruments, apart from the arrangement of the mignon lamp, is in the telescope. That of Nitze slightly magnifies; that of Leiter slightly diminishes. The lenses in Nitze's instrument also give a more perspective picture, to my eyes at least, and cover a larger field—i. e., the observer's eye will perceive with one glance a larger area.△

The drawbacks alleged against Nitze's cystoscope are:◇

\* Author. A Contribution to the Surgery of the Bladder. *New York Med. Jour.*, Feb. 23, 1889.

† That others are of the same opinion is shown by the following passage in a recent treatise by Cecil-Kent Austin, entitled *Sur le diagnostic précoce des néoplasmes de la vessie et du rein au moyen du cystoscope*. Paris, 1890: "Je ferai remarquer en passant que les images perçues au moyen de l'instrument de Berlin m'ont paru plus nettes, plus satisfaisantes que celles que donne l'instrument viennois."

‡ In the new one, which is in my possession, the beak still measures an inch.

# This alteration, as it appears, was first employed by Leiter in the old Nitze-Leiter instrument. *Neue Beleuchtungsapparate mit Zuhilfenahme des elektrischen Lichtes. Nachtrag zu den von Josef Leiter verfassten Catalogen*, 1890, p. 1.

|| I should say here that Nitze demands that Leiter's cystoscope which is practically the same as Nitze's, be called the Nitze cystoscope manufactured by Leiter.

△ Take Nitze's instrument in one hand, turn its prism to the window, and hold the palmar side of the slightly flexed fingers of the other hand at a distance of about two inches from it; then look through the telescope; you will see at once the fifth to second fingers and a part of the ulnar side of the thumb. Do the same with Leiter's cystoscope; you will see only two fingers and a half.

## 1. A somewhat less brilliant light.

It is true, that of Leiter is brighter, because the still longer beak carries a larger, less delicate, and more powerful incandescent lamp. Still, the light as thrown from the Nitze mignon-lamp, if tested as to its strength previous to the introduction of the instrument (what always should be done), will be found entirely satisfactory in every case. Where we can not see with it for special reasons, we shall most probably also not succeed with the other.

2. The silver tip, the carbon filament of which has given out or has been destroyed, has to be sent to Berlin for putting in a new incandescent lamp, whereas Leiter has made the cystoscopist independent.\*

This is now easier arranged for cystoscopists on this side of the ocean, who work with Nitze's cystoscope, as I have induced the W. F. Ford Surgical Instrument Company, 315 Fifth Avenue, New York city, to carry a number of silver tips in stock. Useless tips will there be exchanged for new ones, which fit upon the instrument. (Difference of price here and in Berlin, 50 cents.) I should add, although it is self-understood, that it will be necessary to have a number of these tips, all armed with the carbon filament, constantly on hand, just as the order sent to Leiter should include six reserve lamps. The price of the latter is, however, one fifth of that of the silver tip of Nitze's cystoscope. The difference of the two instruments in this respect is therefore merely a pecuniary one. To replace a burned-out incandescent lamp by a new one does not require a moment longer in Nitze's cystoscope—nay (if such a simple, though important, manipulation is to be compared at all), is even still simpler than in Leiter's. But there is—

3. Another disadvantage, which became manifest to me in the course of the last year, since I have been in possession of three different Nitze cystoscopes. It is that the screw of the different tips in stock will sometimes be found not to fit exactly on the thread at the lower end of the shaft. Thus the screw of the tips now and then overruns the limit of screwing or does not reach it at all. The surface of the lamp then points to another direction than the prism, and the tip is simply useless. It will, however, be seen at once that this is no drawback to the instrument proper, but a mistake which can be remedied at once by a greater accuracy of the instrument-maker. It is to be hoped that Mr. Hartwig will yield to the cystoscopists' urgent requests and pay better attention in the future to this slight but important defect, explained to him at length. The screw-thread of each cystoscope ought to be manufactured *accurately alike*, and the tips, before being sent away, carefully fitted on a standard instrument at Berlin. The arrangement as now made here in New York also dispenses with this annoyance. In cities where a similar arrangement is not or can not be made, the cystoscopist will soon have his small stock of fitting tips, and must insist upon having put new incandescent lamps into these very same tips. I should not omit to state here that, after some experience and with proper care and a good battery, the same tip can be used for nearly a year and perhaps still longer.\*

\* Still I have to mention—

1. To constantly have Nitze's instrument in good working order, it

In his first essay, and later also in his *Text-book on Cystoscopy*,\* Nitze recommended three different cystoscopes for a thorough inspection of the entire inner surface of the bladder.

Cystoscope No. 1, which carries the lamp and prism at its concave side (the latter at the junction of beak and shaft), represents the main instrument, "the" cystoscope.

Cystoscope No. 2, for the inspection of the fundus: The lamp on the concave side; the window at the end of the shaft, through which the observer looks with the telescope; of course, no prism.

Cystoscope No. 3, for illumination of the internal orifice of the urethra and its immediate neighborhood: The lamp and prism on the concave side of the beak, which latter is about half an inch longer than in the others, and bent in nearly a right angle to the shaft. A small mirror, situated at the convexity of the curve inside the tube, reflects the picture which is thrown into the telescope from the reflecting plane of the prism. I have tried this instrument in a number of cases, and can state that the picture seen with it is utterly indistinct. It is to be hoped that it will soon be improved. Although we are able to diagnose the hypertrophy of the prostate "in the picture" with No. 1, yet a thorough inspection of the internal urethral orifice and its surroundings under electric illumination would be very valuable in a number of cases.

In regard to cystoscope No. 2 I can only repeat what I said two years ago: † that it is unnecessary to buy it. I have always succeeded in inspecting the fundus and trigonum, together with the mouth of the ureters, by simply turning No. 1 180° and depressing the handle, even in cases with hypertrophy of the prostate. The inconvenience to the patient is slight. Nitze himself advised me, when I saw him at the International Congress at Berlin, to exchange my No. 2 for a longer No. 1, which would prove very useful in cases of hypertrophy of the prostate, where the urethra is materially lengthened. I did so, and can say that I am very thankful

is absolutely necessary to keep clean and dry the two circular grooves at the upper end of the instrument, as well as the concave surface of the rotatory handle, which, when attached to these grooves, conveys the current from the battery to the instrument. This refers especially to the irrigating cystoscope.

2. The slot key, which, under management of the thumb, serves for opening and breaking the circuit, may work rather easily after some time. The light then will be less brilliant. A simple turn of the screw which holds the key in place will correct this difficulty.

3. If the cystoscope turns too easily in the handle, it will be found useful to leave the left hand at the upper end of the cystoscope, the so-called "funnel," during the examination, while pressing the handle with the other hand tightly against it.

4. If the lamp of a new tip does not burn at once when the current passes its filament, a slight straightening of the little cork-screw-like silver wire at the basis of the tip, before the latter is screwed on, will often be found sufficient to get a bright light.

5. The small bubbles of air which often arise with a peculiar noise from the junction of shaft and tip in Nitze's instrument are caused by the decomposition of the water by the electric current. If a bit of wax is smeared upon the lower groove of the screw at the tip, previous to its being adjusted, this can always be avoided.

\* Wiesbaden, 1889. Verlag von J. F. Bergmann.

† *Loc. cit.*, p. 203.

to Dr. Nitze for this kind advice. The long shaft will be found of advantage in many instances.

As a third instrument I procured the new irrigating cystoscope of Nitze, which permits of changing the fluid in the bladder without being removed itself.\* It contains two small tubes in its shaft, which is thus increased in size to 25 gauge, French. (The size of the beak is 22, as in the others.) The one tube ends just in front of the prism with three small holes side by side. It carries fresh water into the bladder. The water, thrown in with the help of a hand syringe, passes with considerable force over the surface of the prism, thus washing it and removing blood coagula or pus shreds which so frequently settle there and render a successful cystoscopy impossible. This is a very clever arrangement. The other tube ends, or rather begins, with a single oval-shaped opening at one side of the lower end of the shaft; through it the water passes out of the bladder. Both tubes are carried to either side of the upper end of the instrument, and their current can there be shut off by a small stop-cock. Both these stop-cocks are attached below the funnel to a metal ring, which also carries the handle with the slot-key. They thus remain steady in the hand of the observer while the shaft can be turned around its longitudinal axis. The irrigation can be effected without regard to the turning of the shaft. To put the whole into working order, rubber tubes are attached and tied on the end of the two tubes. It will be found of advantage to have the one which carries the water out of the bladder cut so long as to hang into a basin under the table. If the water is changed and the examination continued—which will frequently be of great importance—an assistant or the patient must pump the water in. This latter manipulation is best done intermittently by sudden brief pressures on the handle of the syringe. A fountain syringe can also be used. Of course, this arrangement does not enable us to flush the viscus or wash it out in the ordinary sense. Still, I have found this irrigation sufficient and of the greatest value in clearing up an obscure bladder trouble as well as in the diagnosis of renal disease, pyuria, and hæmaturia. In examining the bladder of patients who suffer from such troubles, the originally transparent medium becomes rapidly and suddenly turbid and the outlook is at once clouded by a dense fog; nothing can be distinguished. I succeeded, in one of these cases where I had to perform nephrectomy for pyonephrosis and cystic degeneration, and therefore wanted to determine the condition and excretory power of the remaining kidney, in establishing the fact, just after fresh water had been thrown into the bladder, that the urine descending from the other kidney was clear (cf. Case III, nephrectomy). In another troublesome case also I could make out only with the help of the irrigating cystoscope that the large amount of pus which always turned the injected water murky in a few seconds was ejected from one ureteral orifice only (cf. Case I, nephrotomy). In fact, I

should prefer to use the irrigating cystoscope mostly were it not that, on account of the increased size of the shaft, its use is only practicable when the urethra is of a certain dimension.

In vesical hæmaturia, where the blood more easily coagulates, the irrigating cystoscope of the present size will often be of little or no use, as the blood-clots generally block at once the canal which carries the water out of the bladder. Fresh water is then pushed into the vesical cavity, but the turbid fluid can not get out.\* If a tumor is to be examined and it does not bleed during the examination, the instrument will also prove valuable in determining the insertion of the growth. The jet of water propelled across the prism and beak will make a pedunculated growth swing, while it leaves the sessile growth undisturbed. (The same result can be obtained in using cystoscope No. 1, by pressing with one hand in sudden short shocks on the epieystic region.)

The irrigating cystoscope will be also found of advantage in cases where papillomatous growths, inserted around the internal urethral orifice, cover lamp and prism of the instrument as soon as it has entered the bladder, and thus render an examination impossible. The field of vision then appears dark. These growths can be easily pushed aside by the forcibly injected fluid, and will then be suddenly seen in bright illumination, swaying in the fluid. Concrements and foreign bodies lying in the pouch behind an hypertrophied prostate gland, and not to be detected there by the examining eye, may sometimes be thrown by the water out of the recessus, and thus diagnosed. Lastly, it is worth mentioning that the irrigating cystoscope enables us to view the bladder in different degrees of distention. In a certain number of cases the ureteral openings can be seen only by this means. (Nitze, *loc. cit.*)

Having thus carefully compared and tried the cystoscopes of Nitze and Leiter, I am ready to say that it is difficult to give proper advice as to which of the two had best be bought by the beginner, as both instruments are equally worthy of being in the hands of everybody who practices electric illumination of the bladder. But, whereas Nitze has given us three useful cystoscopes (according to pattern No. 1), and whereas I deem it of pre-eminent importance, in order to avoid mistakes, to stick to one pattern in the beginning, I prefer to advise the beginner to buy the Berlin instruments. I, personally, have so far gladly incurred the slight annoyance of sending my few burned-out reserve tips to Berlin for repair once in a year. The pleasure of being enabled to work with the three cystoscopes has amply rewarded me. Still, I also often find advantage in using Leiter's elegant instrument in its new shape.

The very newest instrument of this class, which has just been made known to the profession in a preliminary communication, is the *operating cystoscope*, invented by Nitze, and constructed by P. Hartwig, of Berlin (*Centrbl. f. Chirurgie*, No. 51, 1891, p. 993). A cutting forceps is attached, by a peculiar mechanism, to the lower circumfer-

\* *Centrblatt f. Chirurgie*, 1889, p. 949. Nitze had two irrigating cystoscopes made—a "simple" and a "more complicated" one. The former, oval in shape, only permits of throwing more water into the bladder; the latter, which is round, enables us to really change the water. Only the latter is to be recommended.

\* The instrument could be made more useful by increasing the caliber of the tubes and thus, of course, also, of the cystoscope up to No. 30 and more. A female urethra will always, and the male urethra in a few instances or after meatotomy, admit that number.

ence of a cylindrical tube. Its two blades carry at their end a small, sharp scoop. They are opened and closed by a lever, which moves in a longitudinal slit at the upper end

FIG. 1

of the same tube. The whole is slipped on the shaft of the ordinary cystoscope No. 1, and can be moved on it, downward and upward (see Fig. 1 and Fig. 2).

A few more mechanisms of a similar pattern have been designed for intravesical topical treatment.

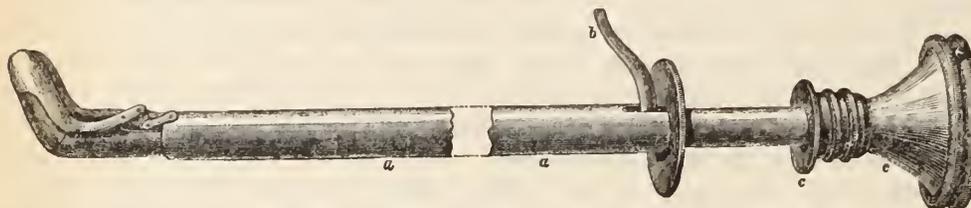

FIG. 2.

To enable one to disinfect these different instruments, and also to make the armamentarium which is needed for intravesical surgery as simple and comparatively cheap as possible, the funnel of the cystoscope has been made movable. It can be screwed on or off the shaft. Thus we can use the same *cystoscope* for all the manipulations, and only need a number of the cylindrical tubes, which carry the proper mechanism. The cystoscope for this kind of work has, besides the movable funnel, a smaller caliber and a longer shaft than the ordinary No. 1. The instrument armed with the forceps has the size of an evacuator as used in litholapaxy; if armed with the other mechanisms, it corresponds to about Nos. 21 to 23 of the French gauge.

Before introducing the operating cystoscope the cylindrical tube, Fig. 2, *a*, is shifted down toward the prism and the forceps, for instance, closed by pressing the lever, *b*, upward. The two blades then surround the beak in such a manner as to form one solid body with it. (The arrangement of the other mechanisms is similar to this.) The instrument will now easily pass a urethra which is not too narrow. As soon as it has entered the bladder the tube is slipped back toward the funnel of the cystoscope (Fig. 1), the light is turned on, the forceps, etc., opened, and everything is ready for work. In looking through the telescope, the motion of the two blades of the forceps or of the cold or red-hot wire of the snare-écraseur can be thoroughly observed and controlled by our eyes.

Thus, an immense progress has again been made. The cystoscope, which hitherto could only be used for diagnostic purposes, is now ready for local intravesical treatment. With the same, if not with more, precision than, for instance, in laryngoscopy, we can make topical application with certain drugs in the bladder without bringing them in

contact with other spots of the vesical mucous membrane; we can cauterize (with the galvano-cautery) ulcers and flat tumors,\* can tear off pedunculated growths with the forceps, can seize and extract foreign bodies, small stones, or the fragments of larger ones, which have been previously crushed. And all this under the direct guidance of our eyes. Indeed, the medical profession, as well as a great portion of suffering mankind, owe thanks to Dr. Nitze for the many brilliant gifts he has bestowed upon them.

In the last three years a few more varieties of the same mechanical principle have been advanced. I will mention these for the sake of completeness:

1. *Hurry Fenwick's Modification of the Leiter Instrument.* †—Part of it has been mentioned above. A further modification is the perforation of the silver cap by three small holes on the side opposite the pane of rock-crystal which covers

the oval window. This is done "to allow of a free current of water to surround the lamp, whereby the hood is kept perfectly cold." In hæmaturia the non-perforated hood has to be slipped on. Fenwick adds in a foot-note: "I break more lamps in the long run, but incur less risk of burning the mucous membrane." In buying a Leiter cystoscope it will be certainly advisable to also order a perforated cap, which is, no doubt, a pretty and sensible improvement, as the larger mignon lamp, situated in the middle of the beak and covered by the rock-crystal pane, heats the entire cap. When in use, the urine or water in the bladder carries off this heat as fast as it is formed, its temperature not being perceptibly raised, even if the lamp is burned for an hour in the bladder. But as soon as it comes in contact with the sensitive mucous membrane of the bladder wall, the patient invariably has a burning sensation. It will be readily understood that a longer unintentional contact, for instance, during narcosis, may really burn the mucous membrane.

The short-beaked Nitze cystoscope carries the incandescent lamp in the tip *uncovered* in direct contact with the surrounding medium. It presents the perforated hood in a peculiar original form. Its lamp does not heat by far as much. In a large number of cystoscopies, with or without anaesthesia, I have so far never had a mishap. The touch of the bladder-wall with Nitze's cystoscope also creates a slight burning sensation.

\* Of course this can not be done if the bladder is filled with water. For such purposes it has to be expanded by air. As Nitze's lamp is situated in the extreme end of the beak, it can burn in the open air for about two to three minutes without spoiling the prism. I presume Nitze intends to proceed in this manner. He promises, in his preliminary article, to give soon full particulars in a more elaborate essay.

† Fenwick, *loc. cit.*, p. 43.

2. *The Irrigating Cystoscope of Berkeley Hill.*—Hill proposed\* to add two small tubes to the lower aspect of the instrument through which irrigation is easily made. The tubes do not greatly increase the caliber.† Nitze's irrigating cystoscope, which carries the tubes inside, seems to offer better advantages.

3. *The "Improved" Incandescent-lamp Cystoscope of Whitehead, Manchester.*‡—The Leiter pattern of 40 French gauge (instead of the usual 22 French); the window of observation and incandescent lamp present double the size, thus increasing the field of vision as well as the brilliancy of light. It is introduced through a median incision in the membranous urethra.

Such an application of the instrument directly annuls the special advantage of cystoscopy—namely, "that it affords a visual diagnosis without a cutting operation." It may, however, be useful and valuable in the female, where the urethra can be easily dilated to No. 40 French.\*

4. *Brunner's Modification of the Leiter Pattern for sounding the Bladder and Catheterism of the Ureters under the Guidance of the Eye.*||—Cystoscope No. 2, of No. 28 French, which carries a separate small channel on the convex side of the shaft. This channel terminates just below the window and can also be used for changing the water in the bladder. It is occluded by a mandrel, when the instrument is introduced. The mandrel later is extracted and replaced by a minute English catheter or an elastic metal sound. Brunner thus succeeded in pushing the catheter into each ureter of a female patient exposed by the light, but failed to do the same in the male. He has had no opportunity to continue his trials in this direction. When the catheter or sound is in the ureter, the instrument itself may be slipped back over it. Perhaps also topical treatment of the bladder could be instituted with this help.

5. *Messrs. F. A. Reichardt & Co., surgical instrument makers, New York city,* have tried to manufacture a cystoscope according to a modified Berlin pattern, which latter bears no international patent. They have, however, not yet succeeded in accomplishing the difficult and expensive task. The instrument which I have inspected at their store was very unsatisfactory in many respects.

6. *The French Cystoscope of Boisseau Du Rocher, of Paris,*<sup>A</sup> is manufactured by Collin, Maison Charrière, of

\* Irrigation of the Bladder in Cystoscopy. *Lancet*, London, 1889, i, 169.

† In a valuable essay of Alexander Stein, New York—Some Points in the Differential Diagnosis of Bladder and Kidney Affections—which appeared in the *Journal of Cutaneous and Genito-urinary Diseases*, 1888, p. 370, I find this passage: "In hæmaturia the injected fluid soon loses its transparency, so that we can see but indistinctly or not at all. I think this latter can be remedied by soldering an oval tube to the bottom of the cystoscope, which would reach to the curve, so that the bladder could be irrigated and refilled without removing the instrument."

‡ *British Medical Journal*, April 7, 1888, p. 768.

\* At Ilurry Fenwick's suggestion, Leiter has made a larger cystoscope of 40 French, to be used exclusively for the female bladder. Its shaft is three inches shorter than in the ordinary cystoscope.

|| Leiter. *Neue Beluchtungsapparate mit Zuhilfenahme des elektrischen Lichtes.* Wien, 1889, p. 9.

<sup>A</sup> Presented by me with the following remarks to the Surgical Section of the New York Academy of Medicine, March 9, 1891.

Paris. In July, 1885, the first report was made about it to the Académie des sciences. But the instrument was not used by others until last year, when Boisseau du Rocher described it at length in an article which appeared in the *Annales des maladies des organes génito-urinaires*, février, 1890.\* He called his instrument "mégalo-scope," and the method of examination for which it was to be resorted to, "mégalo-scopie vésicale." The doctor maintains that his "mégalo-scope" is an entirely new design; that its pattern originated with him independently from those which are already in the market.

To settle this question from the start, it must be said that Boisseau Du Rocher's cystoscope is in its principle nothing else than an elongated ordinary cystoscope of the Leiter pattern No. 2, which is used for an easy inspection of the fundus of the bladder.

In comparison with the latter, the specially striking new features of the Paris instrument are:

A longer beak; a longer telescope, which causes the length of the instrument and in its peculiarities greatly enlarges the spot coming into view; an additional combination of pipes for irrigating the bladder and also for passing the telescope, or passing instruments for catheterism of the ureters.

But the principles in accordance with which the *mégalo-scope* has been constructed are, of course, and had necessarily to be, the same as those brought out in the Nitze-Leiter original cystoscope—viz., the introduction of the light itself into the cavity which is to be examined, and an optic apparatus which magnifies and enlarges the object. The priority of these two devices, which, combined, effected the immense recorded progress in cystoscopy, is due to Nitze beyond a doubt. Any new cystoscopes or endoscopes can only be variations of this original idea.

Further, the medical profession should not accept a new name for Boisseau Du Rocher's instrument and for that which can be done with it. We talk of a laryngoscope and laryngoscopy, of an ophthalmoscope and ophthalmoscopy. We should only have different patterns of a "cystoscope," and one name for the practice created by it—"cystoscopy."

The probable advantages of the Paris instrument, in comparison to the Berlin or Vienna one, as far as I have been able to see them, are the following:

1. That, on account of the length of its telescope, it is six to seven inches longer, and the face of the observer is therefore farther removed from the genitals than is possible in using the other cystoscopes. (But, on account of the great length, a slight motion of the handle will result in a by far greater one of the beak, which thus will often touch the wall of the bladder.)

2. That we can perceive with one glance a larger area and see everything in the same upright position as our eyes would see it without the telescope. (The latter is also experienced in using the Nitze or Leiter pattern No. 2.)

3. That the pipes which run alongside and inside of the

\* See also W. v. Vragassy. Das "Megaloskop" des Dr. Boisseau du Rocher in Paris. *Wiener med. Presse*, 1888, pp. 51 and 90.

lower aspect of the shaft enable us to wash out the bladder before, and apply permanent irrigation during, the cystoscopic examination. There is a wider canal in the center of the instrument for passing the telescope. It is filled out by a steel mandrel while the instrument is introduced into the bladder. If we make use of this canal for irrigation, the viscus can be very thoroughly flushed.

4. That the larger one of the small pipes can be utilized for passing instruments of minute caliber for catheterism of the ureters.\*

5. That the telescope is introduced after the whole instrument has passed the urethral canal—*i. e.*, is in the bladder. The objective lens can thus never be dimmed by an adherent mucous or pus shred or a small blood-coagulum.†

6. That the instrument can be sterilized by boiling water, the cement which is used for fastening the rock-crystal pane in the window of the beak, etc., being such as to stand a great heat. The other cystoscopes can not be boiled. They are disinfected by wiping them very carefully and thoroughly with gauze dipped in a three- to five-per-cent. solution of carbolic acid.

Now, has the French cystoscope also drawbacks as an offset to these advantages? Yes, and very serious ones.

1. We can not inspect the whole inner surface of the bladder with this cystoscope, which, besides, is quite clumsy and not at all as easy to handle as that of Nitze or Leiter.

Boisseau Du Roehér finds an objection to Nitze's instrument on account of the latter's advice‡ to make five exact motions with the cystoscope in the bladder in order to bring into sight every spot of its interior with mathematical exactness. With his own, when introduced into the bladder, the whole fundus, the posterior wall, and a portion of the upper and the two lateral walls come at once into view, without turning or moving the instrument. (In trying to obtain this result we shall, however, get a kind of bird's-eye view.) But to examine the anterior portion of the vertex with the Paris cystoscope, the examining person would nearly have to sit on the floor, and even then the result might not be satisfactory. Therefore two instruments become necessary.

2. The caliber of the shaft is No. 27 of the French scale, that of the beak No. 23. The increase of the size of the shaft is caused by the pipes for irrigation. It is to be mentioned, though, that they are situated at the lower aspect of the shaft, and thus give the tube a conical shape (cf. Brunner's modification). The top of this cone corresponds with the lower circumference of the urethra, which can be stretched. (The size of Nitze's and Leiter's cystoscope is No. 22, that of Nitze's irrigating cystoscope, the shape of which is round, No. 25.)

\* Cf. the Brunner modification.

† Cf. Nitze's irrigating cystoscope. If we make it a rule always to inject some glycerin into the posterior portion of the urethra with the help of a Nélaton catheter right after a careful irrigation of the anterior portion of the urethra, of the neck of the bladder, and of the latter organ itself, and right before introducing the cystoscope, we certainly shall quite rarely meet with this annoying occurrence when using the ordinary cystoscope.

‡ Cf. Nitze's *Text-book on Cystoscopy*, pp. 93-99.

3. The beak is very long—half an inch longer than that of Leiter's, and twice as long as that of Nitze's cystoscope.

4. The angle at the junction of the beak and shaft is  $130^\circ$  and abrupt; in the other two instruments only  $145^\circ$  and well rounded.

5. The lumen of the two pipes used for irrigation and passing catheters for catheterizing the ureters is extremely small. There is at present no catheter in the market, in this city at least, small enough for this purpose.

6. There is no key or screw to make and break the electric circuit. We always have to put in or unscrew one of the conducting wires for this purpose.

7. It is difficult to thoroughly cleanse the inner surface of the objective lens of the telescope. This lens can not be detached from the tube, but has to be reached by a long conductor which holds at its end a piece of maple-marrow.

I have not, so far, succeeded in removing some particles of dust from the inner surface of this lens. A compliance with this need by the manufacturer would mean an improvement of the telescope.

8. The spherical aberration of the lenses of the telescope.

9. A constant dripping of water out of the upper end of the instrument during examination. The intravesical pressure constantly forces the water alongside the telescope, which does not snugly occlude the lumen of the central canal.

So far I have got the impression that the French cystoscope will not as easily come into general use as that of Nitze and Leiter. It decidedly has a few important new features, which will make it desirable for the cystoscopist to be in possession of it. But until the defects mentioned above shall have been remedied,\* we certainly shall always need the additional use of one of the two other cystoscopes in the market if we want to be ready to thoroughly perform a cystoscopic examination in cases where this method can be applied.

In closing this section, a tabulated comparison of the size of the different parts of the three cystoscopes which attract special interest may perhaps be welcome. (See next page.)

In regard to the batteries, a great variety is now at our disposal. Hartwig & Leiter sell a battery with the cystoscope which fully answers the purpose.† The fluid is a mixture of pure chromic acid (to be ordered of Messrs. Churchman & Co., Philadelphia), sulphuric acid, and water (Formula for Hartwig's battery: Chromic acid, 375; sulphuric acid, 300; water, 3,000. For Leiter's: Chromic acid, 500; sulphuric acid, 375; water, 3,000.) The two original Leiter batteries, with hard-rubber cells, are not to be recommended, as they will surely crack and leak after a short while. The repair of such a crack is troublesome and

\* According to a remark of Dr. W. K. Otis, of this city, in the discussion on Dr. L. B. Bangs's paper—Cases illustrating some Difficulties in the Use of the Cystoscope (Section in General Surgery of the New York Academy of Medicine, meeting of November 9, 1891)—this gentleman is at present engaged in improving Roehér's instrument.

always unreliable. Since last year the cells have been made of glass. Thus a very annoying disadvantage is at last eliminated. Fenwick uses a battery supplied by Sehall (London),\* and is pleased with it. He wants a rheostat. For cystoscopists on this side of the ocean I would recommend the cheap and easily manageable, portable, small six-celled battery of the Galvano-Faradic Manufacturing Co., New York city. Not to destroy with it the incandescent lamp at once, the elements must be screwed very slowly and carefully into the fluid until the light is bright. In all these batteries there is no rheostat attached. I so far have never seemed to be in actual need of the latter. In a nearly four years' practice in cystoscopy the number of lamps destroyed by me is a very small one. Still, its presence in a battery will be welcome. A very fine storage battery, Gibson's (three different sizes),† is sold by the W. F. Ford Surgical Instrument Co. It contains four large cells and has a rheostat. Its lighting power is ample.‡ It can be arranged to permit of endoscopic and galvano-caustic work at the same time, which will be found especially convenient in urethroscopy. Recharging once in two to six months;§ in spite of its price, I should advise its purchase by a cystoscopist who lives in a great city.

I still have to call attention to the various attempts which have been made in regard to *fixing the picture* as seen with the cystoscope by *clay or wax modeling, colored drawings, and photography.*

Fenwick, the originator of the first-mentioned method,|| has proved, by the very pretty pictures in his work, how

\* *Loc. cit.*, pp. 46, 47.

† Size I weighs about fifty pounds, and has a capacity of fifty amp. hours; size II, about forty pounds, capacity thirty amp. hours; size III, about thirty pounds, capacity fifteen amp. hours.

‡ The Nitze mignon-lamp requires more electro-motive force (9 to 10 volts) than that of Leiter's cystoscope and urethroscopy (6 volts), because its filament is finer, and consequently offers more resistance to the current. The maximum force of the Gibson four-cell storage battery is eight volts and a fifth. The Ford Co. is now constructing a six-cell storage battery which lights the Nitze lamp also to brilliancy. Its price and weight are of course slightly higher. The manufacturer of the Nitze lamp should build it eight volts or less. This can easily be done.

§ This is, of course, a disadvantage, as it makes us dependent upon the electrician. In houses that are connected with the street electric light system, charging can be done at home.

|| Clay and Wax Modeling of the Living Urinary Bladder under Electric Light, *British Medical Journal*, January 5, 1889; and The Electric Illumination, etc., *loc. cit.*, p. 88.

nice and thoroughly the various pathological conditions of the interior of the living bladder, especially of tumors, if modeled in some plastic material, wax or clay, and then photographed, may be recorded and demonstrated to others who could not attend the examination.

E. Burekhardt very lately gave us a fine collection of colored drawings of bladder images in health and disease; \* every one of them was observed by himself and drawn at once with the cystoscope in position. The *Atlas* will especially be useful to the beginner, and explain to him many a picture which was seen but could not be at once identified.

Instantaneous photography, "the *ne plus ultra* of cystoscopic delineation (Fenwick)," is still in its infancy. Nitze has theoretically laid out an interesting method of best getting a small negative, and then magnifying it. Want of time has not permitted him to make practical experiments. † Géza von Antal, ‡ by his assistant, B. Hermann, published the photographie picture of the cystoscopic appearance of a black hair-pin in a female bladder. It is, however, utterly indistinct.

Fenwick (in connection with Mr. Pearson-Cooper, of the London Camera Club) has succeeded in obtaining good negatives of artificial growths both in the dummy and the dead bladder. But the negatives of the living bladder were too indistinct. A number of certain mechanical obstacles have so far formed an almost insuperable barrier to such a method being successful and practical.

In view of the rapid strides of modern technique, it is to be hoped that these obstacles will soon be overcome and that we shall then be enabled to "graphically record the many new and interesting clinical facts which the electric cystoscope is constantly revealing."

As it seems, this hope has meanwhile already been fulfilled. (See Ueber Photographie innerer Körperhöhlen, insbesondere der Harnblase und des Magens, by Dr. Robert Kutner. *Deutsche med. Wochenschrift*, Berlin, No. 48, November 26, 1891, p. 1311. Kutner is a former assistant of Nitze.)

(To be concluded.)

## CASES OF GALL-BLADDER SURGERY.\*

By ROBERT ABBE, M. D.,

SURGEON TO ST. LUKE'S HOSPITAL;  
PROFESSOR OF SURGERY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

It is superfluous before this society to-night to review the methods advocated for the relief of diseases of the gall-bladder. These have so recently been written upon by Credé, Tait, Kummell, Senger, Gregg Smith, and others, that it will serve our purpose if such observations are made in connection with the unusual features of the cases here recorded as will be suggestive to operators in this field.

Rules for diagnosis and surgical treatment have still to be definitely written, the result of yet to be accumulated experience. Cases of failure and success have further to be recorded before we are masters of the grave accident of complete biliary obstruction.

It is for this reason, and because of the interest attending this line of surgery, that I ask your attention to the unusual cases of which I will speak.

I may say that in general the experience of most operators is favorable to the accomplishment of surprisingly good results in bad cases of obstructive diseases of the gall-ducts, and this is amply borne out by my own four successful cases.

As illustrating the simplest form of operative procedure in cases of obstruction without inflammation, I will first speak of one, done six months ago, and of the ultimate results of which I may now speak with some confidence.

*CASE I. Multiple Attacks of Biliary Colic during Four Months; Exhaustion; Cholecystotomy; Removal of Three Large Gall-stones; Immediate Suture of the Gall bladder; Recovery.*—In April, 1891, Mrs. W., a lady of sixty-four years, came under my care with symptoms of chronic biliary obstruction. She had been for three months under the care of Dr. Partridge, of this city, who had watched her through many severe and constantly recurring attacks of biliary colic.

Her first attack dated to five or six years before. There was then a period of freedom until four months before I saw her, when she was seized with a most severe attack, repeated at intervals of a week or less during the four months following. Each attack was succeeded by moderate jaundice and progressive exhaustion. Though in the earlier intervals she resumed her work, she became too weak during the last month to leave her room.

The usual accompaniment of clay-colored stools and dark bile-stained urine followed each attack.

At last the pain became nearly continuous and she was becoming exhausted. Her skin had a moderate jaundice only, persisting between attacks, though after each severe exacerbation she was quite yellow. I had her removed to a room at the hospital, where poulticing and massage soon relieved the pain and cholæmia, the urine becoming free from bile.

On any attempt to walk, however, pain immediately recurred. There was a moderate tumor the size of an egg at the site of the gall-bladder. A diagnosis of gall-stone obstruction of the cystic duct was made, based on the subsidence of cholæmia with continuance of pain and gall-bladder distention.

I operated April 24th by vertical incision.

The distended and elongated gall-bladder popped out of the wound as soon as the peritonæum was opened, and afforded an

excellent opportunity for handling it without soiling the peritoneal cavity.

Three good-sized stones were found, the largest free, the two smaller ones wedged tightly in the cystic duct. The contents of the gall-bladder showed no suppurative change. The stones were, after considerable trouble, worked back into the gall-bladder and removed.

A small gum-elastic bougie was then passed into the common duct and onward far enough to show all obstruction removed.

I then ventured to do the ideal operation of suturing the incised gall-bladder and returning it into the peritoneal cavity. The mucous and peritoneal coats of the collapsed bladder being œdematous and sliding freely on each other, I thought best to make a separate suturing of each. With fine catgut I stitched the muscular layer so as to invert the mucous edges, and then with finest black silk sewed the peritoneal edges.

The abdominal wound was closed, as usual, in separate layers by buried sutures.

The patient made an uninterrupted convalescence, and left the hospital on the twenty-second day in excellent condition, having gained rapidly in weight, having good digestion, normal movements, and being free from pain.

At the present date (six months after operation) she remains in perfect health, is free from pain, and has resumed her work. The abdominal scar is solid.

This case illustrates the feasibility and safety of the so-called "ideal operation" of immediate suture of the wound in the gall-bladder and replacement in the abdomen.

I believe the absence of suppurative inflammation within it is a *sine qua non* of the procedure. The ability to pass a bougie through the unobstructed ducts may be wanting, for the tortuous and pocketed condition of the cystic duct will often entrap the point of a probe so as to make it impossible to pass it through even a pervious canal. In such a case one might fill the gall-bladder with fluid after removing the impacted calculi, and, by pinching the incised wound, observe whether the fluid can by pressure be emptied into the intestines. If so, I see no reason why the immediate suture should not be resorted to.

It has been observed that a comparatively large sound will pass through a sacculated duct when a small probe will be entrapped. In one case I was unable to pass either a large or a small one, yet the duct was pervious. In another such case I would try fluid, and, if pervious, I would prefer to suture and return to the abdomen.

*CASE II. Gall-stone with Suppurating Gall-bladder and Enormous Thickening, simulating Cancer; Cholecystotomy; Recovery.*—In April, 1889, F. M., a young married woman, came under my care for progressive debility and hectic, with a tumor of the right side below the ribs. There had been a vague history of colicky pain before the tumor began. She had not been jaundiced. The tumor had been noticed for five or six months. It was at this time apparently as large as one's fist and quite movable, lying in the direction of the gall-bladder. The mass was tender to pressure, and had been diagnosed as a cancer. Believing it to be an empyema of the gall-bladder, I did laparotomy in the usual site, and, much to my surprise, came upon a solid tumor occupying the exact site of the gall-bladder, and running backward so as to include the ducts in the mass.

Adhesions to the adjacent parts were present.

In spite of its very malignant look, I thought best to make a

\* Read before the New York Surgical Society, October 14, 1891

free incision into it, to relieve, if possible, any pent-up source of sepsis from which I judged her to be suffering. The incision only seemed to confirm our fears. The massive and hard walls were from an inch to an inch and a half thick, and in gross appearance resembled and cut like carcinoma tissue. The remnant of the gall-bladder cavity was a small channel holding only two drachms of muco-purulent fluid. No foreign body could be felt within it.

I therefore established a fistula from it through the abdominal wall, and gave the patient rather an unfavorable prognosis.

During the next few weeks she made an easy convalescence. The sinus, however, did not close, but the mass remained quite as evident to external palpation as before.

Six months afterward she returned to me to see if the sinus could not be closed.

I was surprised to find her in restored health. The sinus secreted copious mucous discharge, but, on probing, it no longer led into an indurated mass. The tumor was no longer to be found. In the sinus was a gall-stone, incrustated with phosphate, the size of a pecan nut. This I removed.

The sinus promptly healed, and some months afterward I had an opportunity of examining her side, and could find no trace of tumefaction. The patient was in robust health.

This extraordinary hyperplasia of the walls of the viscus presented a strikingly deceptive appearance of malignancy. It has been occasionally observed by others, but no explanation has been offered of why it should occur in one case more than in another.

CASE III. *Cholecystotomy and Removal of Fifty-three Stones, followed in Six Months by Cholecystectomy and Removal of One Stone more.*—Mrs. L. B., aged twenty-nine years, admitted to St. Luke's, October, 1888, with the following history:

Ten years previously she had her first attack of gall-stone colic. It was followed six months later by another, three months later by another, and afterward almost every month for many years. The intervals ranged from two weeks to three months. The attacks were agonizing, and she had acquired a morphine habit in consequence. Jaundice had supervened on several of the attacks, but she had no chronic jaundice. She had become emaciated physically and discouraged morally.

The region of the gall-bladder was tender on palpation, but no tumor could be felt. Even her corset pressure was painful.

I operated on October 8, 1888, by the vertical incision. The gall-bladder had old, intimate adhesions to the stomach, which being dissected off, I secured its presenting end by two loops of silk stitched through its wall before opening, and evacuated fifty-three small and large calculi. The fluid in the gall-bladder was thin, whitish mucus.

Although no probe could be passed into the common duct nothing could be felt suggestive of stone, either within by probe or without by palpation of the duct. The gall-bladder was stitched in the wound. The patient made a quick recovery and went to her home in Maine with a sinus not yet healed.

Six months later she returned with the sinus still discharging a mucous fluid without bile, and having had moderate recurrences of pain.

I advised reopening the abdomen to explore the cystic duct and remove the atrophied gall-bladder.

No calculus could be felt by palpating or sounding the cystic duct. I therefore dissected the gall-bladder from the liver and from adherent colon and stomach and ligated it close to its junction with the hepatic duct.

On cutting it away, I found that a calculus the size of a pea

was locked between two strictures of the duct, and had been the evident cause of continued pain.

The wound being now clean, the abdominal wound was closed at once.

The lady made an immediate recovery of her health, and all pain ceased from that date.

A letter received two days since from her physician states that up to the present date, *three years* since operation, she has remained in perfect health, without the least recurrence of pain.

I was impressed in this case with the difficulty of discerning by the touch of a silver probe the soft surface of a gall-stone. I doubt if one can know in any case whether all stones have been removed except by the touch of the finger within the gall-bladder.

I was also pleased to find the dissection from the surface of the liver not a difficult or serious matter. There had been enough inflammation in past years to cause more intimate union with the liver than the usual cellular tissue. Yet the hæmorrhage was readily controlled by pressure.

The fourth case is one of great interest.

CASE IV. *Impaction of Gall-stones in the Hepatic, Cystic, and Common Ducts for Two Years and a Half; Profound Cholæmia; Removal of Gall-stones and Gall-bladder; Recovery.*—A. C., aged thirty-six years, was in excellent health until two years and a half since, when she was first seized with biliary colic and became gradually jaundiced. The colic was soon relieved, but her jaundice increased, and during the entire period has only grown worse and worse. At times she seemed almost black with it, as she expressed it, yet she continued to work at her occupation of dress-making. She lost flesh, and now weighs thirty pounds less than she did. Since the first attack she had indigestion and vomiting frequently, but never of blood. Her stools have been clay-colored and her urine like porter. Two months ago she had a renewal of the biliary colic, which she characterizes as "terrible," but it diminished in one week. She has grown quite unlike her old self, in being subject to nervous attacks, and occasionally has what resembles *petit mal*, losing consciousness for a few moments. She presents the most intense form of jaundice in her face, body, and mucous membranes. The complexion is rather of a blackish-green than yellow, owing to prolonged staining and pigmentation. The liver is very much enlarged, extending two inches below the free border of the ribs. A tumefaction can be felt somewhat deeply at the site of the pylorus, quite hard and suggestive of malignant or inflammatory growth.

During abdominal palpation over this portion, the patient on every occasion was seized with semi-epileptic, semi-hysterical attacks, at first groaning, then lapsing into unconsciousness, with muscular contractions—evidently from pressure near the solar plexus, in a woman profoundly cholæmic. The patient was altogether in a poor condition, with five per cent. of albumin in her urine and hyaline casts. After consultation with my colleagues, I operated, April 13th, under ether. The vertical incision was used. Adhesions of the stomach to the gall-bladder and liver hid it from view, but after careful dissection it was released. Several moderate-sized calculi could be felt through the walls of a rather small gall-bladder, as well as in the cystic duct, and one, as large as a walnut, farther down in the common duct. The bladder was opened and some viscid bile escaped. The stones being removed from the gall-bladder, it became necessary to incise the cystic duct to release others.

No amount of manipulation availed to move the largest one in the common duct. An attempt was made to crush it ex-

ternally, but without effect. I therefore split the wall of the common duct in continuation of the cut in the gall-bladder and duct, and found the large stone locked between two strictures of the duct. It being removed, a bougie passed readily into the intestine through the duct.

I then sewed up the cut of the duct with finest black silk, and cut away the gall-bladder and its duct entirely, leaving only the greatly dilated hepatic duct, into which the finger readily passed and from which stones were removed.

The engorged liver poured out large quantities of healthy bile during my manipulation. To control the discharge I introduced a large rubber drain into the hepatic duct, running it upward into the liver a short distance. Over this I passed a larger tube, which terminated at the site of the junction of the ducts, and around it I packed a small iodoform gauze tamponade—the object being to divert all the bile from the liver out of the abdominal wound, and after a few days by removing the inner tube to let the larger one remain to drain the sinus—thus leaving the bile free to travel along the common duct as soon as swelling had subsided.

This device worked admirably, and surprising quantities of bile were poured out during the first two days. Her jaundice soon began to clear perceptibly. The urine cleared at once.

Seidlitz powders were given the second and third day with good results.

At the end of a week she suffered an attack of acute dry pleurisy, from which she slowly recovered.

On the ninth day the first bile tinged her stools. One week later she had a sloughing abscess of her back, from no apparent cause. This retarded her convalescence.

In four weeks she sat up, ate well, and was losing the jaundice, but had a bronzed skin from pigmentation.

At the end of four weeks a fistula only remained in the side, through which most of her bile escaped. Having seen abundant evidence of bile in the stools, I ventured to have the fistula strapped. Immediate and complete closure and healing followed.

In five weeks her bile was all pursuing its normal course, and she was entirely well, except for color, which was slow to leave. During the summer she has resumed work, and is in perfect health again at the present time, her color having now become perfectly natural.

This case shows that intense cholæmia is not necessarily as fatal an element in operable cases as has been commonly taught. The operative method I have adopted is by the vertical incision over the site of the gall-bladder, and I believe that thus more extensive exploration can be made than by any other method.

The last case I will mention is that of a man with chronic obstructive cholæmia from a small malignant growth just within the outlet of the common duct. This man was for many weeks under medical care in St. Luke's Hospital before being transferred to my service. He was profoundly jaundiced and suffering from an exhausting hectic fever. His liver was enlarged to three inches below the ribs and a considerable tumor of the gall-bladder was perceptible. The most marked feature in the history of his illness was the absence of an initial attack of colic. This in itself was presumptive evidence of malignant obstruction. The distended gall-bladder with grave hectic warranted the diagnosis of empyema of the gall-bladder. The suppurating gall-bladder was found and relieved by the usual operation. No stone or malignant disease was found. The gall ducts were impassable to small or large probes passed into the gall-bladder. The probability of a stricture or other obstruction at the duo-

denal end of the common duct led me to search for this through an incision into the duodenum; this I made two inches and a half long and, as I supposed, about four inches and a half from the stomach. Most careful search and palpation failed to reveal the site of entrance of the duct into the duodenum, and the incision was closed by a continuous Lembert suture. Drainage of the suppurating gall-bladder was therefore all that was accomplished. The man survived one week. Post-mortem examination showed the duodenal incision to have been four inches below the site of the duct. A small, soft malignant growth was attached to the wall of the duct just within its lower end, and acted as a valvular stricture. It was scarcely large enough to be perceived by palpation through the intestinal walls at the post-mortem. From this origin, however, multiple secondary deposits of cancer were found in the liver and lung, some of them as large as a hen's egg.

The case illustrates the comparative ease and safety with which the duodenal end of the common duct can be examined by proper incision into the duodenum. Had there been any stone or growth of considerable size in the lower end of the duct, it would certainly have been felt by the finger within the intestine and could have been removed.

In conclusion, I would emphasize the fact that the four cases of obstructive disease from gall-stones here narrated were all progressing to a fatal end and the patients were all restored to perfect health by operation, the time elapsing since operation being from six months to three years.

## DISEASES OF THE URINARY APPARATUS.

BY JOHN W. S. GOULEY, M. D.,

SURGEON TO BELLEVUE HOSPITAL.

(Continued from page 95.)

### PART I.—PHLEGMATIC AFFECTIONS.

#### SECTION II.—SPECIAL CONSIDERATIONS.

##### X.

#### ACCIDENTS, COMPLICATIONS, AND CONSEQUENCES OF THE ACUTE TYPES OF URETHRITIS.

WHEN exempt from accidents, complications, and consequences, urethritis resolves in four or five weeks, or, if primitive and in a young healthy subject, may be cured in eight or ten days. It is principally in this second class of cases that the rapid cures are so frequently reported, while the accidents, complications, and consequences are too often ranked by themselves as if they had no connection with urethral phlegmasia. It is therefore necessary, in the management of urethritis, to keep in mind the liability of the occurrence of the accidents which may arise from the imprudence, carelessness, or neglect of the patient; of the complications which aggravate the urethral phlegmasia; and of the consequences of unwise, untimely, or rash treatment. Not many years ago was still in vogue the routine treatment of "gonorrhœa," consisting in the administration of large doses of copaiba or cubeb, and in the use of strongly astringent urethral injections, without regard to the type or stage of the phlegmasia. The frequency of accidents and of more or less grave sequelæ was then great as compared to what it is at present. The

rational treatment, based as it is upon a sounder pathology and more accurate diagnosis, seems now to be so firmly established that these accidents and sequela occur with markedly less frequency than in former times, and are much better managed.

The accidents of acute urethritis are urethral hæmorrhage and conjunctivitis. The complications to which acute urethritis is liable are balanitis, posthitis, and balanoposthitis, the last causing or aggravating phimosis, and the forcible retraction of the narrowed and swollen prepuce producing paraphimosis. The consequences of acute urethritis are lymphangitis, inguinal adenitis, peri-urethritis, cryptitis, bulbo-urethral adenitis, prostatitis, orchitis, gonocystitis, trachelocystitis, pyelitis, nephritis, septicæmia, pyosapremia, rheumatism, chronic urethritis, and urethral stenosis.

ACCIDENTS OF URETHRITIS.—*Urethral hæmorrhage* during acute urethritis is ordinarily due to frequent and prolonged erections of the penis, to masturbation, or to coitus, and is not an uncommon accident. It is rarely abundant, and ceases spontaneously in the majority of cases. Preventive and afterward repressive means should be promptly employed, for the reason that hæmorrhage indicates here a solution of continuity of the mucous membrane, and therefore liability to a rapid stenotic process. Profuse hæmorrhage is rare and generally due to "breaking the chordee" in superacute urethritis. It usually ceases spontaneously in the course of thirty-six hours, but sometimes continues several days, much to the detriment of the sufferer. Active measures should therefore be taken to suppress the flow of blood. If cold fails when applied externally or by way of intra-urethral irrigations, it is wise, without further delay, to introduce a urethroscope as far as the seat of hæmorrhage, to wash away the blood with iced water, and to touch the bleeding spot with a camel's-hair brush previously dipped in persulphate of iron solution, and then to irrigate once more in order to be sure that the hæmorrhage is checked. The patient should be kept quiet in bed, cold external applications continued several hours, and other suitable means taken to prevent erections, but the parts should not be meddled with any further, for the more handling, the greater the liability to recurrence of the hæmorrhage. Internal pressure by the introduction and maintenance in position of a large catheter has been recommended in these cases, but this should be avoided except in the most extreme circumstances. The presence of such a foreign body becomes almost intolerable, and in the course of three or four days is liable to cause ulceration of the mucous membrane, and even perforation of the urethra and urinary fistula.

*Virulent conjunctivitis* arises from the accidental contact of pus from virulent urethritis with the conjunctiva. The pus may be conveyed to the eye by a soiled hand or through some other medium, such as a towel or cloth polluted with urethral pus. The right eye is oftener affected than the left, and both eyes are very rarely involved. This phlegmasia, commonly called "gonorrhœal ophthalmia," is, fortunately, an extremely rare accident of urethritis, for it

is ordinarily superacute. Though it may resolve in a few days under suitable treatment, leaving but slight traces of its occurrence, its sequela are frequently refractory to treatment, and sometimes fatal to vision. Its progress is occasionally so rapid that the eye perishes in a few hours after the first symptoms. It is characterized at its outset by some itching of the edges of the lids, by a sensation as if a small foreign body had lodged beneath the eyelid, and by great increase of lacrymation. Then follow much turgescence of the conjunctival capillaries, chemosis, intense pain in and around the eye, annoying photophobia, and a profuse flow of pus. The chemosis sometimes increases so rapidly as to strangle and destroy the cornea before medical aid can be obtained.

The main features of the treatment employed by experienced ophthalmic surgeons is here given to guide the general physician in whose practice cases of virulent conjunctivitis occur, for the salvation of these inflamed eyes depends upon the promptness and efficiency of the treatment which should be forthwith begun, to be vigorously continued until the arrival of an expert ophthalmologist, with whom the responsibility of the further management of the case is shared. But, inasmuch as an ophthalmologist may not be accessible for several hours, or even for a day, as in small towns, the general physician should render himself competent to manage cases of virulent conjunctivitis to the end. For his own protection he should, at his first visit, make a note of the exact condition of the eye, and have some person to witness this examination of the eye and of the writing of the memorandum, which he should sign and the witness should countersign.

The treatment of this violent phlegmasia should be most prompt and energetic, the prime indication being to check the rapid phlegmasic process and thwart its destructive tendency. In the early stage, and then only, free local depletion should be effected through leeches applied to the temple close to the outer canthus of the eye. The instillation of atropine solution should at once be begun, to be continued to the end of the phlegmasic process. Copious catharsis should be induced. The patient should be placed in a dark room and his sound eye properly protected, but the inflamed eye should not be covered. A nitrate-of-silver solution, sixty grains to the ounce, should be applied once each day to the whole conjunctival surface with a camel's-hair brush, and immediately washed away. When chemosis appears, free cuts should be made through the conjunctiva radiating from the cornea's edge. But what is most efficient and most to be depended upon to relieve the chemotic pressure upon the eye is free section of the external canthus, including the dense aponeurotic layer, and this simple operation can not too soon be employed in cases of extreme chemosis. Almost incessant ablutions of the eye during the first forty-eight hours should be made with cold, mildly astringent antiseptic solutions, and this eye kept under the watchful care of a trustworthy and faithful nurse, who shall obey strictly the physician's directions. After forty-eight hours, or after the danger of strangulation of the cornea is passed, the ablutions need not be so frequent and the nitrate-of-silver solution may be weaker,

but still used once daily until the conjunctival membrane appears normal. If the whole cornea have already sloughed, the eyeball should be extirpated as soon as expedient after the termination of the phlegmasic process.

COMPLICATIONS OF URETHRITIS.—*Balanitis*—phlegmasia of the glans penis, involving the mucous membrane, the spongy substance, or both—is characterized, in the first case, by an itchy and burning sensation, more or less intense redness, swelling, and at length a purulent discharge. It may be of the same nature as, or may have appeared before, the urethritis, by which it is intensified, particularly when caused by the accumulation of smegma. In superacute urethritis there sometimes occurs an abundant plastic exudation in the substance of the glans penis, which swells and becomes very tense. Resolution is slow or is not accomplished, and the imperfectly organized exudate undergoes sclerous degeneration, causing irregular shriveling of the glans. Subacute balanitis, with plastic exudation and induration of the glans, is often the outcome of violent, careless, and unduly frequent catheterism. The induration thus caused is most apparent around the urinary meatus, and is in some cases so strongly marked as to be mistaken, at first sight, for malignant disease.

*Posthitis*—phlegmasia of the foreskin of the penis, affecting its mucous layer, its cutaneous layer, or both of these layers—sometimes exists independently of balanitis, but, as a general rule, is associated with balanitis and is designated as balano-posthitis. Posthitis occurs frequently in young subjects affected with vesical stone, causing frequent and painful urination and subacute urethritis; this frequent escape of urine, and the traction upon the prepuce made by the sufferers in endeavoring to obtain relief, being the exciting cause of the posthitis. The foreskin is elongated, sodden, swollen, red, and painful, and its mucous membrane emits pus and sometimes blood. This sodden condition of a long prepuce in the adult occurs in cases of urethral stenosis and obstruction to urination from other causes, leading to unduly frequent urination, or to constant dribbling of urine.

Infibulation of the prepuce—a device of very ancient date, to insure continency among the young until the age of twenty-five, described by Celsus, practiced extensively in the middle ages, condemned by Dionis and others during the seventeenth century, seriously recommended within the last fifteen years as a cure for “epilepsy and seminal loss”—is still occasionally, but secretly, employed. It is hurtful not only on account of its favoring the accumulation of filth, but of the irritation excited by the buckle, which is liable to induce posthitis with so much induration of the foreskin as to lead to the suspicion of malignant disease. Dupuytren relates such a case which at first he believed to be cancer of the prepuce. The jealous mistress of the patient had succeeded in inserting an ingeniously contrived gold ring through the end of the foreskin and had locked it. In the course of time the extremity of the penis was so much enlarged, indurated, and painful, that the ring was removed; this afforded relief from the pain, but the swelling and induration were slow in yielding to treat-

ment. The parts finally regained in a measure their normal state.

*Balano-posthitis* is generally due to the accumulation of smegma beneath a long prepuce, but at times it begins with the attack of urethritis, and is even superacute and associated with lymphangitis. The mucous membranes of the glans and prepuce are tumid, of a vivid red, very sensitive, and emit a considerable quantity of pus. In extreme cases, complicated with phimosis, these mucous membranes ulcerate in patches, so that when cicatrization is accomplished the two surfaces adhere permanently unless precautions are taken against the occurrence of such adhesion.

*The treatment of balanitis and balano-posthitis*, in cases where only the mucous membranes are involved, and the prepuce is short or easily retracted, consists in thoroughly cleansing the glans and prepuce with antiseptic solutions three or four times daily, and after each washing to cover the affected parts with a thin layer of a powder composed of equal parts of oxide of zinc and boric acid, or else aristol, or euprophen, which is said to be an iodide of isobutylorthoeresol, and which does not possess the objectionable odor of iodoform. Ointments are not tolerated in the majority of cases.

*Phimosis*.—Balano-posthitis complicated with phimosis not being amenable to treatment by powders, the preputial cavity should be irrigated with antiseptic fluids two or three times daily until the subsidence of the phlegmasic process. If the prepuce be only long enough to cover the glans penis, divulsion of the preputial orifice may be employed to relieve the constriction; but if this orifice be extremely narrow or its edges much indurated, postotomy will be the more efficient procedure. This operation consists in making a longitudinal incision through the skin and mucous membrane of the prepuce on its dorsal aspect, so that the glans can be easily exposed. The edges of the skin and mucous membrane should then be stitched together, so as to obtain a transverse scar from the longitudinal incision, and thus increase the size of the preputial opening.

When the prepuce is long and so narrow as to render its retraction difficult or impracticable, posthectomy should be performed, but not until the subsidence of the phlegmasic process, unless the integrity of the glans be imperiled by the existence of chaneroids. This minor operation, performed for many thousand years largely as a religious rite, consists in cutting away the superabundant foreskin and enough of its mucous membrane to permit the glans penis to be easily uncovered. As a religious rite the greater part, if not the whole prepuce, is removed. For the purposes of the surgeon it is rarely necessary to make a complete posthectomy. The operation is the same in principle as it has ever been, but its details have undergone many hundreds of modifications. The essential steps of posthectomy are—1, to pull gently forward the prepuce; 2, to apply a suitable clamp to retain it in position and to protect from injury the extremity of the glans penis; 3, to quickly cut away all that part of the prepuce isolated by the clamp; 4, to remove the clamp and slit the mucous membrane longitudinally not more than half an inch; 5, to trim with scissors the angles of the mucous membrane; 6, to take proper

means to arrest any oozing of blood or, if necessary, to tie bleeding vessels; 7, to stitch the mucous membrane to the skin with very fine silk or with horse-hair; and 8, to apply a light dressing to the parts. In very young subjects no stitching is necessary. Ordinarily the wound heals primarily.

*Paraphimosis*, an accident of phimosis, occurs from the forcible retraction of a narrow prepuce for the purpose of cleansing the glans, or during coition or masturbation. It is then very difficult or impossible for the patient to bring forward the retracted prepuce, owing to swelling of the glans penis. When paraphimosis has existed several days it is not possible sometimes, even after section of the constricting ring, to replace the foreskin. Ordinarily it is rather an inconvenient and unsightly deformity than a dangerous condition, for the glans penis is very rarely damaged by an irreducible paraphimosis. A portion of the dense ring into which the retracted prepuce is converted finally sloughs and the strangulation ceases, but the adhesions which take place forbid the ultimate reduction of the prepuce.

The reduction of the retracted prepuce in paraphimosis can generally be effected by compressing the glans penis and pushing it backward while the prepuce is, as it were, unrolled upon the glans, using for this purpose the thumb and index and middle fingers of each hand. This process is applicable only before the glans penis has become very tumid. When the tumefaction of the glans is such as to forbid reduction by this method, a simple and quick process is to apply elastic compression by means of a bandage, one inch wide, of thin India-rubber, such as dental surgeons use under the name of rubber dam. Compression so made expels the blood from the glans and sufficiently decreases its size to permit of reduction of the retracted prepuce. The last turns of the bandage should be applied to the œdematous prepuce to expel the serum from the meshes of its connective tissue. The bandage is not removed from the glans penis until the reduction is nearly complete. It has been proposed to relieve paraphimosis by placing the patient on his back, grasping the penis with one hand, and striving thus to lift him. This is said to have been practiced on children as well as on adults. The violence of this remedy is such as to make it worse than the discomfort which it is designed to relieve, for the traction incident to the effort of raising the whole body by the penis is so great as to seriously injure the urethra, and possibly also the cavernous bodies.

CONSEQUENCES OF URETHRITIS.—*Lymphangeitis* of the larger subcutaneous lymphatic vessels of the penis occurs in consequence of slight injuries, of friction by the clothing during exercise, or of the untimely use of urethral injections. The phlegmasia may be subacute, acute, or superacute.

Subacute lymphangeitis is characterized by its indolence, by the slight engorgement of the subcutaneous lymphatics, and by a little œdema of the neighboring connective tissue. It is a frequent consequence of acute urethritis and may appear during the first ten days or not until the decline of the phlegmasia. It rarely suppurates and resolves under rest and simple lotions in the course of four weeks.

Acute lymphangeitis is characterized by longitudinal reddish tracts in the course of the lymphatics, which are tense, nodulated, and tender to the touch, from the preputial frænum to the inferior inguinal glands where they terminate. The prepuce is much swollen from serous exudation, and sometimes the whole phallic integument is in the same tumid condition. This type of lymphangeitis very rarely suppurates, and resolves in the course of three or four weeks under absolute rest in recumbency and soothing lotions.

Supercute lymphangeitis is characterized by a diffuse erysipelatous redness and swelling of the integument of the whole penis. Although it most frequently resolves under the same management as the acute type, it is sometimes followed by abscesses in the course of the lymphatics, and in very rare instances by diffuse suppuration, requiring free and early incision. In still more rare instances the phlegmasia is propagated to the cavernous bodies of the penis (phallitis), and leaves a certain amount of induration which deforms the penis during erection. This plastic exudation in the cavernous bodies sometimes undergoes calcareous infiltration, a condition often miscalled bony transformation of the penis.

*Inguinal adenitis* often follows lymphangeitis of the penis consequent upon urethritis, but it also occurs without there being any lymphangeitis, and may appear as a consequence of any of the forms of virulent urethritis or of simple non-contagious urethritis. One or more than one gland may be inflamed. The phlegmasia may resolve after a few days of rest, may be indolent, or suppuration may ensue. This form of adenitis is one of the varieties of non-syphilitic buboes; there being two varieties, one of which resulting from chancroids of the penis or urethra, the other from non-infecting urethritis. These buboes are ordinarily on a level with or a little below Poupart's ligament, and may be unilateral or bilateral. In the event of suppuration, the diseased glands should be freely incised, and in some cases excised.

*Peri-urethritis* arises as a consequence of acute, but more frequently of superacute, urethritis, the phlegmasic process extending itself to the submucous connective tissue or even to the spongy substance, and occupying a part or the whole circumference of the urethral canal. It occurs in the perineal, in the serotal, or in the phallic region of the urethra, most frequently in the last-named region. It is often provoked by untimely urethral injections, by the so-called abortive treatment of benign urethritis with strong solutions of nitrate of silver, by violence to the inflamed urethra such as may occur from coition or from masturbation, or by any ingested substance which may render the urine acid. It is characterized by a more or less abundant plastic exudation in the submucous connective tissue, or both this and the spongy substance. The exudation may occupy the whole extent of the inflamed part of the urethra or may be confined to one or several isolated points, causing much pain during erection and, to a greater or less extent, curvature of the penis (chordee). When the exudate retains its semi-fluidity it may soon be absorbed, or may end in suppuration and peri-urethral abscess. The abscess opens oftener in the urethra than externally. In the latter

case the urethra may be perforated and a urinary fistula thus established. When the exudate is partly organized, sclerous degeneration begins and urethral stenosis is the sequel. This sclerous degeneration may be so rapid that in a few months the lumen of the urethra is reduced to the point of admitting only a capillary bougie, or it may be so slow that five, ten, twenty, or even thirty years may elapse before the caliber of the urethra is sufficiently reduced to attract the attention of the sufferer.

In the treatment of *peri-urethritis* the first indication is the discontinuance of the injections which may have provoked the phlegmasia. If balsamics had already been administered, they too should be discontinued. The patient should be confined to bed for five or six days, and means taken to abate the frequent and painful erections of the penis which so much aggravate the phlegmasic process. An evaporating lotion, or, better, dry cold, by mediate irrigation, as suggested by Petitgand, applied through India-rubber tubing of small size and thin walls, coiled around the penis so that a continuous flow of water at any desirable temperature may be used without wetting the bed or otherwise inconveniencing the patient, has the double effect of preventing erections and of acting as a local antiphlogistic. The urine should be rendered bland by the administration of diluent drinks, and five grains of gum camphor, one grain of hyoscyamus extract, and five grains of taraxacum extract, made into a bolus, should be taken at bed-time and, if necessary, once again during the night.

When these means fail to induce resolution, and suppuration ensues, the peri-urethral abscess opening in the urethral canal, it is necessary to take measures to prevent the entrance of urine, rare as this occurrence may be, into the abscess cavity for two or three days, or until the formation of granulation tissue. This is effected by the passage of a small, soft catheter whenever urination becomes necessary. If the abscess points externally, it may be incised, or, if small, the few drops of pus it contains may be removed by aspiration, as advised by Christian Smith. For this purpose the ordinary syringe employed for hypodermic injections may be used. This simple process, perhaps repeated two or three times, tends to prevent urinary fistula. Should it, however, fail, a sufficiently free external incision is indicated.

When resolution is slow or when the exudate, instead of leading to suppuration, becomes more consistent, with a tendency to undergo organization, the oleate of mercury, applied daily along the under surface of the penis or the perinæum, according to the site of the peri-urethritis, is of much advantage. In obstinate cases the oleate of mercury may be replaced by vesicating collodium once every week until this vesication has been used three or four times. Internally the bromides of sodium, ammonium, and potassium, two grains each, should be given in a wineglass of water four times a day for a week or ten days.

Resolution failing, the peri-urethritis becoming chronic, or sclerotic degeneration beginning, which is the same as saying that a stenotic process is established, the most efficient method of treatment, designed to prevent the formation of a narrow stricture, is free dilatation of the urethra once a week continued several months.

*Urethral cryptitis*—phlegmasia of the mucous follicles of the urethra—a common consequence of acute urethritis, is often very persistent and sometimes constitutes the main cause of chronic urethral discharges. It occurs most frequently in the balanic region, but may affect one or many follicles in any part of the urethral canal. It happens occasionally in acute urethral phlegmasia that the mouth of a follicle becomes occluded by swelling of the mucous membrane. Purulent accumulation ensues, distends the follicle, and forms a small, hard, globular, or ovoid abscess, containing only four or five drops of pus, which is finally discharged into the urethra, or externally through a very narrow orifice. This orifice does not always close, and there remains a fistulous tract through which some urine escapes. To prevent the formation of a fistula, an attempt should be made to open the mouth of the inflamed follicle with a slender probe, such as the smallest used in stenosis of the lacrymal ducts, so that the pus may escape in the urethra. This failing, aspiration is made as in periurethral abscess, or even external incision. The treatment of chronic cryptitis will be considered under the head of chronic urethritis.

*Bulbo-urethral adenitis* is a rare consequence of acute urethritis. This phlegmasia having already been described, it is now only necessary to thus briefly notice it as a consequence of acute urethritis.

*Prostatitis*, having also been described, requires no further examination.

*Orchitis* is used as a generic term to signify a phlegmasia affecting any or all of the divisions of the testicle. Epididymitis is the term commonly used for phlegmasia of the summit of the testicle, and didymitis for phlegmasia of the body of the testicle, the latter occurring rarely. Of 222 cases of epididymitis consequent upon urethritis observed by Fournier, 164 were from acute urethritis and 58 from chronic urethritis. Of the 164 cases from acute urethritis, 6 occurred during the first ten days of the urethritis, 15 on the eleventh day, 34 during the third week, 30 during the fourth week, 29 during the fifth week, 19 during the sixth week, 9 during the seventh week, and 21 during the eighth week. Of the 58 cases from chronic urethritis, 22 occurred during the third month, 1 during the seventh year, and the remainder scattered between the fifth month and the fourth year.

*Epididymitis* is a frequent consequence of urethritis. It occurs in about thirty per cent. of all cases of acute urethritis, and generally appears on or about the third week from the beginning of the urethritis—*i. e.*, during its period of decline, or after it has reached the prostatic region. However, this extension of the phlegmasia to the prostatic region sometimes occurs in a few days after the beginning of the urethritis, particularly if the urethritis begins in the prostatic region. In either case, epididymitis may begin very soon after the development of urethritis. It arises from extension of the phlegmasic action, by continuity of mucous membrane and lymph-vessels, through the ejaculatory duct and spermatic canal, and thus reaches the epididymis. In some cases the phlegmasic action is most intense in the spermatic canal, and is even propagated by

the lymph-vessels to the spermatic cord. In these cases there is sometimes little swelling or pain in the epididymis, while at other times the epididymis is much swollen, very painful, and accompanied by perididymitis, the pain extending to the inguinal region and even to the abdomen. These last are cases of superacute epididymitis.

A young man affected with superacute epididymitis complained, on or about the third day, of severe pain, extending from the testicle and spermatic cord to his abdomen, which soon became distended. This was the beginning of a sharp seizure of peritonitis, from which he, however, recovered. A little reflection as to the explanation of the attack of peritonitis led to the conclusion that the canal between the peritoneal cavity and the tunica vaginalis, formed in fetal life by the descent of the testicle, had remained patent, and that the phlegmasia of the tunica vaginalis, consequent upon the epididymitis, had through this channel extended itself to the peritonæum. It is worth while to take into account the possible existence of such an anomaly in case of peritonitis arising in connection with epididymitis, though it is also possible for peritonitis to occur by transmission through the medium of lymph-vessels.

Phlegmasia of the epididymis may be developed slowly and gradually in six or eight days, or may be superacute and reach its height in twenty-four hours. It is often attended with febrile reaction and gastric disturbance—furred tongue, nausea, vomiting, etc. Ordinarily, however, it attains its maximum of intensity in the course of three or four days. Both testicles rarely suffer at the same time. The phlegmasic action may affect only that part known as the tail of the epididymis, may be extended to the body, or may be most intense in the head of the epididymis. This same phlegmasic process frequently involves one or both seminal vesicles. Suppuration is a very uncommon result of epididymitis. Resolution occurs on or about the third week; but there often remains some induration at one or two points at the head or toward the tail, or the whole of the epididymis becomes sclerosed, and finally shrivels. Epididymitis occasionally recurs several times in the course of three or four months on the same side, and sometimes on the opposite side—*orchite à bascule* (Ricord). These recurrences are apt to be owing to the existence of small abscesses in the substance of the epididymis.

One of the occasional consequences of bilateral epididymitis is sterility. This is owing to chronic phlegmasia of both spermatic canals, the acid pus destroying the spermatozoa. In some cases these canals become completely occluded by a gradual stenotic process, with destruction of the epithelium, or by pressure from without at the tail of the epididymis during the shriveling of a phlegmasic nodule.

Several patients who had suffered bilateral epididymitis married healthy women, whom they have never succeeded in impregnating. One of them married a second time, and his wife, a well-formed woman in excellent physical condition, had not become pregnant ten years after.

*Didymitis* and epididymitis are specialized because, in the first case, the phlegmasia sometimes scarcely affects the

epididymis, but expends itself on the body of the testicle, and, in the second case, because often the spermatic canal is very little affected, and the body of the testicle is intact, while the epididymis is the center of the phlegmasic process. To warrant this specialization there are other reasons, among which may be mentioned that didymitis sometimes arises from direct violence to the body of the testicle, and that this didymitis is said to occur secondarily to parotitis and to variola without epididymitis.

Didymitis, consecutive to epididymitis, may be subacute, acute, or superacute. It may resolve in three or four weeks, may suppurate, may end in gangrene of the testicle in two or three days, or become chronic. Superacute epididymitis is almost always attended with perididymitis, and sometimes with parenchymatous didymitis. In either case there is true orchitis, all the divisions of the testicle being affected.

*Subacute parenchymatous didymitis* is attended with little pain, but is slow in resolving, and liable to recur every few weeks. These recurrences forebode the development of purulent foci in the testicle. After three or four recurrences of dull pain and a sense of tension in the testicle, the two layers of the tunica vaginalis become adherent anteriorly or laterally. This is evidence that an abscess is approaching the surface. It happens that in some cases a single abscess is formed, becomes encysted, and is not recognized until the diseased testicle is removed and cut open, when a central mass of cheesy pus is enucleated.

*Acute parenchymatous didymitis*, though very painful, the pain extending from the testicle along the spermatic cord to the inguinal and even to the lumbar region, generally resolves with the accompanying epididymitis, and very rarely suppurates. Sometimes resolution fails and the phlegmasia becomes chronic. The seminiferous tubules are then plugged with plasma, and the intertubular substance is soon involved, sclerosis and shriveling of the testicle ensuing. This is not an uncommon occurrence in cases of didymitis consecutive to parotitis. There is a type of didymitis in which the testicle remains indurated for many months, and finally breaks, by ulceration, through the bounds of its tunics and integument, and is extended as a fungoid mass, named benign fungus, sometimes mistaken for syphilitic or for tubercular disease. Benign fungus occurs among persons whose health is much deteriorated by debauchery and its consequences. This so-called benign fungus consists of no other elements than those composing the testicle in a state of chronic phlegmasia, together with a covering of granulation tissue.

*Superacute didymitis is of rare occurrence.* It is attended with very great pain and much febrile reaction, reaching its maximum of intensity within forty-eight hours, when the fate of the testicle is decided, for after this the phlegmasic process is on the decline or the testicle is in a gangrenous state. The whole body of the testicle is affected, the intertubular as well as the tubular substance. Its form and size are unchanged, the fibrous tunie yielding no space for swelling, hence the occurrence of gangrene, the hardness, and the almost intolerable sense of tension experienced by the sufferer. Even when the tes-

ticle escapes gangrene it is likely to be otherwise injured, for it either suppurates or ends in chronic induration, sclerous degeneration, and shriveling.

THE TREATMENT OF EPIDIDYMITIS should be adapted to the degree of the phlegmasia and to the peculiarities of individuals. Fretful, hyperæsthetic, algophobic patients affected with the mildest epididymitis are sickened by what others regard as a minor degree of pain, and require to be tranquillized by free doses of the bromides or even of opium. Otherwise the mild cases need nothing more than rest and suspension of the testicle. Other patients affected with superacute phlegmasia, endangering the testicle, make little or no complaint, though they experience much pain. In these cases prompt antiphlogistic treatment and the closest attention are necessary to save the testicle.

*Acute epididymitis* demands free catharsis, rest in the horizontal posture, and the ice-bag for forty-eight hours, or perhaps longer. There are cases in which cold applications fail to relieve pain; in these, hot fomentations often have the desired effect in the course of a few hours. The testicle should then be swathed in a thick layer of carded cotton sprinkled with half an ounce of tincture of opium, and the whole well suspended. In case of phlegmasia of the spermatic cord with much pain, a small plaster composed of powdered opium (one drachm) and a sufficient quantity of water to make a thin paste should be applied over the inguinal canal, as recommended by Velpeau, after ten or twelve leeches have extracted as many ounces of blood from that region. As a general rule, poultices should not be used; they are particularly hurtful in cases complicated with scrotal dermatitis. When there occurs effusion of serum in the tunica vaginalis (acute hydrocele), attended with much pain, relief is very soon afforded by making fifteen or twenty punctures with an exploring needle, the serum escaping in the scrotal connective tissue. "Strapping" is worse than useless and is sometimes destructive to the testicle. The patient should be kept in the horizontal posture for at least a week, and the testicle properly supported during that time and for two or three weeks thereafter. When suppuration has taken place in any part of the epididymis free incision should be made without delay.

THE TREATMENT OF DIDYMITIS is essentially the same as that of epididymitis, except in the case of the superacute type, which demands more heroic antiphlogistic measures, beginning with the application of at least sixteen leeches in the inguinal region on the affected side. Then the ice-bags—one anteriorly, the other posteriorly, as suggested by Curling—should be used continuously night and day for four or five days. Sufficiently free doses of opium, or of morphine hypodermically, to blunt the senses and induce sleep, are absolutely necessary. The prime indication is to prevent the occurrence of suppuration or of gangrene of the seminiferous tubules. When the violence of the phlegmasia is expended, when the pain is relieved, the affection is to be dealt with as in the case of epididymitis. But when, in the course of thirty-six or forty-eight hours, the faithful use of

ice and of the other antiphlogistic agents fails to subdue the phlegmasic process, and the sense of tension is rapidly increasing, a free incision should be made through the scrotum and tunica albuginea. This is imperative as the only means of increasing the space for swelling or of re-establishing the local capillary circulation and thus preventing necrosis of the seminiferous tubules. The patient has a right to the benefit of the doubt, if any doubt exist in the mind of the physician as to the expediency of the procedure at the particular time, by a prompt resort to this incision, for even a brief delay may be fatal to the integrity of the testicle. This seemingly violent mode of treatment was advocated about fifty years ago by Vidal (de Cassis), who afterward wished to generalize it in all forms of orchitis, and made incision of the tunica albuginea, and even of the parenchyma of the testicle, in four hundred cases. He was criticised with undue severity by Gosselin, who asserted that the incision scarcely ever extended beyond the tunica vaginalis, and that the relief experienced by some of the patients so treated was owing to the exit of serous fluid which had distended the tunica vaginalis and had been the chief cause of the pain. Vidal did, however, accomplish incision of the tunica albuginea and often found the testicle already necrosed. In such cases incision is surely indicated. Hernia of the seminiferous tubules is liable to occur after incision of the tunica albuginea, but better this than gangrene, for under favorable circumstances cicatrization follows, though the testicle is more or less damaged.

(To be continued.)

## A CASE OF SO-CALLED LARYNGEAL VERTIGO.

By I. ADLER, M. D.,

VISITING PHYSICIAN TO THE GERMAN HOSPITAL, NEW YORK.

THAT peculiar, though somewhat varying, group of symptoms which, following the lead of Charcot, is commonly designated as laryngeal vertigo, is still a subject of discussion as regards both its pathology and its ætiology. The well-authenticated cases thus far reported are comparatively few in number. Scarcely more than two dozen cases have been reported since Charcot first called attention to the affection in 1879, and the authors differ widely in their interpretation of the clinical facts. Under these circumstances every new case of so rare an affection becomes valuable as possibly shedding some light on a point hitherto doubtful or obscure. From this point of view I venture to present the following case:

Mr. J. E. H., aged about fifty-three, merchant. No hereditary taint of any kind. With the exception of several attacks of gonorrhœa, claims never to have had venereal disease. Minute examination detects no evidence of syphilitic lesion. Does not use tobacco in any form. Is accustomed to take several glasses of wine or beer with his meals. He is a man of florid complexion and robust and healthy appearance. He professes never to have had any serious illness, but is subject to "colds and coughs." From time to time during the last few years he has shown slight but sufficiently well marked symptoms of a gouty tendency and has had occasional attacks of muscular

rheumatism. About three years ago he had an attack of acute bronchial catarrh with little or no febrile symptoms, accompanied for several days by thin, foamy, and not very copious bloody expectoration. No pulmonary lesion could be detected, and the sputum then and since remained free from tubercle bacilli. The slight hæmorrhage was referred to congestion of the bronchial mucosa. In November of 1890, in the course of a slight bronchial catarrh attended by rather violent paroxysms of cough, he claims during one of these coughing spells to have suddenly "fainted." Being hurriedly called in and arriving a few minutes after the attack, I found the patient apparently perfectly well and bright. Questions addressed to him and to the members of his family who had witnessed the attack elicited the following facts: The paroxysm of cough had been no worse than usual. He was in a sitting position when the cough seized him, and during the coughing he arose as if to expectorate, then suddenly fell to the floor, totally unconscious. He claims to have noticed no premonition of any kind. There was no giddiness; he was not conscious of any tickling or burning or other sensation about the larynx. The bystanders were unable to state whether the face was pale or turgid or livid. There was no cry, no involuntary micturition, nor were any convulsive twitchings noticed. The unconsciousness lasted but a very few seconds. The patient raised himself without assistance from the floor, laughed at the alarm expressed by his family, felt no lassitude, sleepiness, or any discomfort whatsoever. Careful examination showed some dry râles in the larger bronchial tubes, slight hyperæmia of the pharynx and larynx, and an elongated uvula, otherwise no lesion of any kind. The bronchial catarrh, accompanied by still rather violent paroxysms of cough, passed away in about a week, but no further seizure like the one described occurred. The treatment consisted in the administration of opiates and expectorants.

I desire to note here a peculiarity in Mr. H.'s manner of coughing which struck me whenever I had occasion to see him for one of his periodical attacks of coughing. It seems as if he had acquired a habit of "choking" over his cough whenever the paroxysm is even moderately severe. The chin is depressed so as almost to touch the sternum, head and shoulders stoop forward, the face becomes turgid and red, the superficial veins swell out, and the cough consists of a deep inspiration, succeeded by a number of short, spasmodic expiratory movements following each other in rapid succession, and differing only from pertussis in lacking the long sibilant inspiration which commonly ends the paroxysm in the latter.

During April of this year Mr. H. had an attack of influenza, and following this, after the febrile stage had passed, a very violent cough. At first there were all the symptoms of diffuse bronchial catarrh, sonorous râles over the entire chest, mucopurulent expectoration, etc. Later on the râles gradually vanished, the expectoration diminished, and finally at the end of about ten days ceased altogether, but the cough remained more violent than ever, and assumed a more spasmodic character. The peculiar habit referred to above was still more marked. The cough came in paroxysms, during both day and night, seriously interfering with his sleep. It commenced with tickling in the region of the throat and larynx, became at once very violent, accompanied by turgidity of head and neck, lasting from some seconds to several minutes, and ended usually with the expectoration of a small lump of glassy mucus, sometimes, however, without any expectoration. This state of things continued for about a week, sinapisms, opiates, expectorants, and inhalations being administered without any apparent effect on the paroxysms of coughing. One evening during a violent coughing spell, which occurred while Mr. H. was standing upright, he suddenly dropped to the floor utterly unconscious. I was called

in at once and arrived a few minutes after the seizure. There had been no premonitory signs. The cough commenced with the usual tickling in the upper air-passages, but did not apparently differ from any of the preceding paroxysms. There had been no giddiness. The patient did not feel that anything unusual was going to happen. He simply dropped to the floor, almost immediately to arise again, feeling perfectly well, but not aware of any unusual occurrence.

The physical condition now was the following: Very moderate granular pharyngitis, elongated uvula, slight hyperæmia of the larynx, heart and lungs in normal condition, pulse full and regular—between 60 and 80 beats per minute. The pupils of equal size and reacting normally. Ophthalmoscopic examination negative. No appreciable symptoms on the part of the nervous centers. The knee-jerk somewhat subnormal, but still sufficiently well marked. The urine, which was examined frequently and carefully, at no time showed albumin, casts, or sugar. The quantity of phosphates and urates was slightly in excess of the normal. No other abnormality could ever be detected. Opiates had been given before; they were now administered in larger doses. No attack during the next two days; then another one of exactly the same character as before, with merely this difference: that, happening to recline on the sofa, he did not fall to the ground, but simply lost consciousness. As opiates had been of no service, they were now replaced by large doses of the bromides of sodium and ammonium, and a competent laryngologist made daily applications of a spray to the pharynx and larynx. The attacks of sudden loss of consciousness following cough now appeared daily, soon several times during twenty-four hours, by night as well as by day. During one of these attacks about this time Mr. H. slightly bit his tongue. The seizures evidently becoming more frequent and more severe, the local treatment, after about ten days of spraying, was discontinued. By the desire of the patient and his friends, the advice of a very well known neurologist was obtained. On recommendation of the latter, iodide of sodium was added to the bromides, and both gradually increased up to ten grammes *pro die*, also gradually increasing doses of the red iodide of mercury, blisters to the back of the neck and laryngeal region, and large doses of cerium oxalate. This treatment was continued for about three weeks. Under the influence of the bromides the pharynx and larynx became quite anæsthetic, and the patient stupid and somnolent. There were marked symptoms of iodism. The seizures, however, steadily increased both in violence and frequency. He had now as many as four or five in twenty-four hours. In one of these attacks, which came upon him while descending from one floor to another, he fell down stairs and was badly bruised. In another he dropped while standing with a friend in the street and severely hurt his face.

It is to be noted that, while no seizure ever took place without preceding cough, by no means every violent paroxysm of cough was followed by loss of consciousness. The daily coughing spells were quite numerous—sometimes several dozen in twenty-four hours—but, as far as I have been able to ascertain, he never had more than five seizures attended by loss of consciousness in one day. Nor were always the most violent fits of coughing followed by these peculiar attacks. Not infrequently a very violent paroxysm would pass without further consequences, while a comparatively rather mild cough would send the patient into unconsciousness. It is stated, too, that in several instances, when the state of unconsciousness had been of somewhat longer duration than usual, slight convulsive twitchings of the eyes and arms were noticed just before consciousness returned.

As the patient was evidently getting worse, all this treatment was now stopped; no medicine whatever was adminis-

tered, and when, after about six days, the local effect of the iodide and bromide had completely disappeared, another very careful general and local examination was made. The result of the general examination proved entirely negative. Locally the same appearances were found as above stated. The larynx was carefully examined with a probe, in order to determine the presence of any hyperæsthetic spot as the origin of the convulsive coughs. No such spot was found. As no tangible point of attack could be made out in the larynx, as medicinal treatment had plainly and completely failed, and bearing in mind the experiences of Gleitsmann, who had cured a similar case by removing adenoid vegetations at the base of the tongue, and of Charcot, who effected a cure by cauterizing a granular pharyngitis, I determined to clip the uvula. This was done at once. The patient went home and had no attack for twenty hours; then two very slight ones in rapid succession, and none since then. The cough continued for some five or six days, having completely lost its spasmodic character, and then disappeared altogether.

The preceding history has been given at great length because it seems to offer several points of interest. We have here a man without organic lesion and of fairly good health, who, after a moderate attack of bronchitis, becomes subject to spasmodic cough, attended by frequent seizures of complete loss of consciousness. There is no aura preceding the seizure, no cry, no involuntary micturition, no hebetude or confusion of mind on regaining consciousness. Unfortunately, it so chanced that I was never able to observe an attack in person. It is therefore impossible to say what was the behavior of pulse and heart during a seizure. The members of Mr. H.'s family, who witnessed quite a number of these sudden losses of consciousness, were invariably startled and alarmed to such a degree as to render them unfit for the purposes of closer observation. It was impossible even to make out with any degree of certainty whether the patient was red or pale in the face. Altogether the witnesses tend more toward the belief that the face was red and turgid. The patient himself describes his sensations during a violent paroxysm of cough as "choking," as "wishing to cough, and not being able to cough out"—a sensation evidently very similar to that described by the patient of Russell.\* It seems reasonable to assume from all this that the spasmodic cough was frequently followed by spasm of the glottis. That for this latter the elongated uvula was principally responsible would seem to follow from the failure of all other treatment and the prompt relief from all symptoms after the clipping. In what manner the uvula produced the spasm can not be positively ascertained. I am inclined to assume that it was by direct irritation of the *rima glottidis*. The patient's peculiar attitude while coughing would tend to raise the larynx sufficiently to permit this, while the fact of these spasms occurring frequently at a time when the pharynx and superior portions of the larynx were well under the influence of bromide anæsthesia would seem to preclude any other mode of mechanical irritation. It is not impossible that the attack of influenza which preceded these spasmodic seizures may have induced a more than ordinary irritability of the nervous system, and that this may explain why former attacks of cough were never,

\* *Birmingham Medical Review*, vol. xvi, August, 1884.

with but a single exception, followed by similar complications.

Leaving out of consideration those cases in which similar attacks have occurred in the course of locomotor ataxia, as so-called laryngeal crises, and where well-marked anatomical lesions have been found in the track of the pneumogastric and recurrent,\* we find widely differing opinions as to the nature of this singular neurosis. Charcot † is inclined to accept this group of symptoms as a disease *sui generis* and analogous to Ménière's disease, the afferent nerve in this instance being the superior laryngeal. Gray ‡ and Massei § consider these attacks to be essentially epileptic. Others again, such as McBride, || Russell, ^ Knight, ¶ and Gleitsmann, † explain the loss of consciousness and attendant symptoms by disturbances of circulation in the brain, basing their views on the well-known experiments of E. F. Weber. ‡

It is not my intention to enter into a detailed discussion and criticism of these conflicting opinions, nor to give an exhaustive review of the cases thus far recorded. All this has been done most fully and ably by Thernes, ¶ Knight, and others. In the case of Mr. H., the complete loss of consciousness and the absence of all vertigo and even giddiness, as well as of nausea and vomiting, seem to preclude all analogy to Ménière's disease. There seems no necessity of ranging our case under the head of reflex epilepsy. No spot or nerve could be found by the irritation of which it was possible to produce an attack. Nearly all cases of well-authenticated reflex epilepsy present well-marked convulsive seizures with all the classical symptoms preceding and following the convulsions. Interesting in this respect are the cases of Schneider.\*\*

The oft-quoted case of Sommerbrodt, †† in which a large fibroid of the left vocal cord apparently caused true convulsive attacks of epilepsy, can not be considered here, as the patient had had epileptic attacks fifteen years before which were at that time referred to a cicatrix on the right hand and disappeared after the excision of the scar. Evidently this was a case of well-marked "epileptic disposition."

It seems as if all the symptoms in our case could be satisfactorily accounted for by the experiments and theory of Weber. Forced expiratory movements with a spasmodically closed glottis caused increased intrathoracic pressure.

Ultimately not only the heart itself to a certain extent, but principally the *venæ cavae* are compressed, the flow of blood to the heart is diminished and then ceases, a condition of arterial ischaemia and venous hyperaemia ensues in the brain. The pulse becomes weaker and finally disappears altogether, and the heart's action comes to a standstill unless, before this climax is reached, the glottis is reopened and normal respiration is resumed. That this mechanism can and does produce complete loss of consciousness with total amnesia, and even convulsive twitchings, within a fraction of a minute is established by Weber's experiments on himself. All the conditions given by Weber were present in the case of our patient—the spasm of the glottis with violent, rapid expiratory movements, the turgid face and neck, etc. Had it been possible to obtain a satisfactory record of the pulse and heart, or even of the pulse alone, during one of the seizures, the question could have been settled beyond peradventure. As it is, the case appears in all essential respects analogous to Thiermes's second case, where the pulse and heart during the spell of unconsciousness were found so characteristically in accord with Weber's results.

Being still completely ignorant of the true anatomical lesion underlying epilepsy, and the experiments of Kussmaul and Tenner and others making it at least probable that disturbances of cerebral circulation play an important rôle in the pathology of epilepsy, there can be no objection, if one was so inclined, to call the peculiar seizure of laryngeal vertigo epileptoid—epileptoid attacks, however, resulting not from a hypothetic irritation of a peripheral nerve, but from great and sudden disturbance of cerebral circulation.

Finally, it is perhaps worthy of note that in the present case again, as in so many before recorded, there is a history of gout and rheumatism. That in all hitherto recorded cases, with but one exception (the second case of Knight), the patients are males, of whom the large majority had passed their fortieth year when they became subject to these attacks, are facts that must be taken into account in the future study of this affection.

**The Medical Society of the State of New York.**—Dr. J. H. Glass, of Utica, the chairman of the committee on credentials, announces that the committee will be in session, together with the treasurer, at the Delavan House, Albany, on Monday evening, February 1st, to facilitate the registration of members and delegates.

**The Alvarenga Prize of the Paris Academy of Medicine.**—According to the *Lancet*, Dr. Frederick Bateman, of Norwich, England, whose views regarding the localization of the speech center have been mentioned in the *Journal*, received the award on December 15th, for his treatise on *Aphasia and the Localization of Speech*. The prize was divided equally between him and Dr. Leguen, of Paris. There were twenty-five competitors, the prize being open to all comers.

**The Death of Dr. Stanislas Zalewski, of Bordeaux, France,** is reported in the *Progrès médical*. He had reached the patriarchal age of one hundred and eleven years. He was born at Warsaw in 1780, but had lived in France since boyhood. He retired from practice thirty years ago, subsisting on a slender pension allowed him by the French Government. Until quite recently his health had been excellent, and all his faculties unimpaired.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JANUARY 30, 1892.

### MOLIÈRE AND THE MEDICAL PROFESSION.

THE presidential address presented at the last meeting of the Ohio State Medical Society deals with that greatest satirist of the medical profession, Molière. Its author is Dr. Conklin, of Dayton, and the address may be found in the *Transactions* of the society, just issued.

Molière's true name was Poquelin, Molière being that adopted by him during the ten years of his life when he was a strolling player. It was some time in the year 1658, when he was thirty-six years old, that Molière emerged into the sunshine of court recognition. Then it was that the long-coveted opportunity, an invitation to play before the king, came, and grandly did Molière's genius plume its wings for dramatic flight. During the fifteen years that embraced the true career of the dramatist, the favor of Louis was unshaken, and it was rewarded by that brilliant series of comedies which mark an era in French literature. In that time Molière composed thirty pieces, half of which are classical. The later ones are the best, for in them he found the true field of his genius—the portraiture of the Tartuffes, Sganarelles, Dandins, Argans, and other perennially true types of human character.

Dr. Conklin's contention is in Molière's favor as against the views commonly pronounced by the critics. Nearly all commentators assume that Molière was actuated by an implacable rancor against physicians and their calling. A careful study of his writings, of the friendly tenor of his life, and of the state of the times will prove that this harsh indictment has been overdrawn. The two great objects of the dramatist were the selfish one of maintaining court favor and the intellectual one of exercising his creative faculty as poet and comedian. If he failed to keep the king amused and to make the people laugh at his characters, he would be relegated to the strolling profession. His genius impelled him to chastise the shams and hypocrisies of his time. He hated cant and pedantry, and attacked every station of life, from the highest to the lowest, that exposed these frailties to his view. Without rancor, with very little of avoidable personality, and without partiality, he made the nobles, the Church, the doctors feel the sting of his satire where they were most vulnerable. "The shafts of his humor, like the arrows of Tell, pierced the foibles at their center, without wounding head or heart."

Molière had not a few intimate friends among the physicians of the court, some of whom were under discipline by the Faculty of Medicine for the use of antimony and other chemical innovations. Molière had very little of sarcasm to expend upon the faction addicted to the antimonic "irregularity," but the phlebotomists of the academy are never spared. They are ordinarily represented as ignorant pretenders, speaking in

mongrel Latin like that which, in *Le malade imaginaire*, is put into the mouth of the candidate who has a stereotyped answer for all questions about the treatment of diseases:

“Clysterum donare,  
Postea seignare,  
Ensuita purgare,”

and in the event that this treatment fails, he next replies: “Reseignare, repurgare et reeclysterisare.”

Medical sects and dissensions abounded, and physicians carried on their controversies with all the acrimony of theologians. The sick-room was the scene of many an unseemly quarrel, from the death-bed of Cardinal Mazarin down to the cot of the coachman. These scenes were the legitimate prey of the satirist, and they became immortal in the text of *L'Amour médecin* and *Le malade imaginaire*. The latter was composed by Molière when his health was rapidly failing and the shadows were gathering about him. It is a dying comedian's sarcasm on the impotence of the medical art against life's last ebb. His health had been precarious for six years; he was annoyed by cough and hæmorrhages, due either to aneurysm or to pulmonary phthisis. “How much a man suffers ere he dies!” was his weary exclamation when on his way to the theatre on the evening of his death. Under these circumstances, and others of an embittering nature, it is not surprising that he gave vent to satire and bitter invective against the art that failed him at the pinnacle of his genius and renown. “You have a doctor,” said the king to him when they were walking together in the royal garden, “what does he do for you?” “Sire,” he replied, “we walk together, he prescribes remedies which I do not take, and I get well.” But medicine may be said to have obtained a poetic revenge against Molière, since his death-blow fell upon him in immediate connection with his fourth rendering of the *Malade imaginaire*. He was taken violently ill while on the stage, and was carried to his deserted home, where he died in less than an hour, suffocated by a pulmonary hæmorrhage. He thus literally materialized the dismal prediction which he had put into the mouth of Argan, in the play last mentioned, when saying that Molière would get only his deserts if the physicians “would let him die without medical assistance.” He died without assistance, but not for the reason stated by Argan, “and that will teach him another time not to make fun of the Faculty.”

To sum up the case as stated by Dr. Conklin, Molière was a man of genius, with many traits of true nobility; he hated a lie, a sham, a miser, and a bigot. He could not fail to see the foibles of his time, and he had the courage and ability to chastise them. “Nothing was too humble or too sacred for his purpose. The doctors were fair game and easy to ridicule. Everybody, when well, laughs at doctors, and no one—not even the doctors—is seriously the worse for it.”

### MINOR PARAGRAPHS.

#### SEPTIC PNEUMONIA IN THE NEW-BORN.

In the *Archiv für pathologische Anatomie und Physiologie und für klinische Medicin*, Dr. O. Lubrasch and Dr. H. Tsutsui

report interesting post-mortem findings in the case of an infant two days after birth. The autopsy was performed thirteen hours after death, and revealed pleuritis and pneumonia of the left upper lobe, bronchitis of both sides, and atelectasis of the right lung; parenchymatous infiltration and uric-acid infarction of the kidney; fat infiltration and congestion of the liver; an enlarged spleen; and icterus. The microscopical examination of the organs revealed the presence of Gärtner's bacilli in great numbers. These micro-organisms were found in the vessels of both lungs, between the cells and the fibrinous masses of the pneumonic exudation, and in the fibrinous effusion in the pleura. The spleen contained numerous patches of micro-organisms similar to the typhus bacilli. These were also found in the kidney, in the glomeruli and intertubular capillaries. None were found in the mucous membrane of the intestines. Cultures were made from material taken from the lungs and spleen, and then inoculated into rabbits and guinea-pigs, and the condition brought about in these animals proved the nature of these germs. Gärtner declared these bacilli to be identical with those that he had previously described. It was thought at first that the case was one of Winckel's disease, as the important clinical symptom of hæmoglobinuria was present, followed by genuine septicæmia, until the finding of the Gärtner bacillus. It was a matter of considerable wonder how these organisms had entered the child's system, as every possible avenue of entrance, such as the umbilicus and the intestines of the infant and the external genitals of the mother, were examined with negative results.

#### THE TREATMENT OF DEBILITY, ANÆMIA, AND RICKETS.

A VERY common error in the treatment of diseases of defective nutrition is pointed out by Dr. Cheadle in the July number of the *Practitioner*. It consists in relying wholly or chiefly upon drugs. Children are dosed with iron, phosphates, or cod-liver oil without regard to the condition of the digestive functions or their fitness for the reception of such materials. A delicate child is condemned to cod-liver oil because it is flabby and anæmic, without regard to other conditions. Perhaps the appetite is poor, the tongue is coated, and the bowels are constipated. The chief cause of the symptoms in this case is to be found in the disordered state of the functions of digestion, absorption, and excretion. Cod liver oil and iron are invaluable in their proper place, but here, by intensifying the digestive difficulty and diminishing the appetite, they are likely to do more harm than good. A few doses of gray powder, followed by a tonic with some saline laxative, will be far more effectual. At the same time the diet must be carefully regulated. When the digestive disorder has been removed the oil, iron, and phosphates may be found of the greatest value in completing the cure in rickets. Plenty of fresh milk and cream, raw meat juice, fresh air, and sunlight are better medicines than any to be found in the pharmacopœia.

#### BORO-BORAX.

ACCORDING to *Lyon médical* for January 3d, this is a compound, discovered by Jaenicke, formed by mixing equal parts of borax and boric acid in boiling water. It is a crystalline, neutral body, of great solubility in comparison with boric acid, sixteen per cent. dissolving in cold water, about thirty per cent. in water of the temperature of the blood, and seventy per cent. in boiling water.

#### LAVAGE IN THE TREATMENT OF ILEUS.

DR. AUFRECHT, in the *Therapeutische Monatsheft*, says that the method of treatment from which he has had the best re-

sults is to give a dose of morphine subcutaneously at once, and then to introduce an œsophageal tube into the stomach and irrigate with large quantities of water. By this means the gas is allowed to escape, the distention got rid of, and the stomach cleared of its abnormal contents. In some instances but one irrigation has been sufficient to relieve the distress and quiet the patient. He advises the giving of the morphine hypodermically in every instance, as in this way its action is much more prompt in arresting spasm. The patient should be kept under its influence and the irrigation repeated if distention reappears.

RESECTION OF THE LIVER.

ACCORDING to the *British Medical Journal* for January 10th, Professor Tansini, of Modena, in extirpating a hydatid cyst of the liver found it necessary to excise a portion of hepatic tissue. There was free hæmorrhage from the cut surface of the liver that was controlled by catgut ligatures; the hepatic wound was closed by silk and catgut ligatures, and the patient was well within a fortnight.

ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending January 26, 1892:

DISEASES.	Week ending Jan. 19.		Week ending Jan. 26.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	9	6	8	2
Scarlet fever.....	242	33	211	26
Cerebro-spinal meningitis....	4	2	2	3
Measles.....	152	9	128	9
Diphtheria.....	115	46	122	38
Small-pox.....	0	0	11	0
Erysipelas.....	2	0	5	0
Varicella.....	9	0	18	0
Pertussis.....	0	2	0	2
Leprosy.....	0	0	1	0

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 17 to January 23, 1892:*

BRECHEMIN, LOUIS, Captain and Assistant Surgeon, will proceed without delay from the Presidio of San Francisco, Cal., to Vancouver Barracks, Washington, and report in person to the commanding officer of that post for temporary duty.

APPEL, AARON H., Captain and Assistant Surgeon, is relieved from duty at Fort D. A. Russell, Wyoming, and will report in person to the commanding officer, Fort Buford, North Dakota, relieving CABELL, JULIAN M., First Lieutenant and Assistant Surgeon, who will then report in person for duty at Fort D. A. Russell, Wyoming.

Society Meetings for the Coming Week:

MONDAY, *February 1st:* New York Academy of Sciences (Section in Biology); German Medical Society of the City of New York; Morrisana Medical Society (private); Brooklyn Anatomical and Surgical Society (private); Utica, N. Y., Medical Library Association; Cornin, N. Y., Academy of Medicine; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Hartford, Conn., Medical Society; Chicago Medical Society.

TUESDAY, *February 2d:* Medical Society of the State of New York (first day—Albany); New York Obstetrical Society (private); New York Neurological Society; Elmira, N. Y., Academy of Medicine; Buffalo Medical and Surgical Association; Ogdensburg, N. Y., Medical Association; Hampden, Mass., District Medical Society (Springfield); Hudson, N. J., County Medical Society (Jersey City); Androscoggin, Me., County Medical Association (Lewiston); Baltimore Academy of Medicine.

WEDNESDAY, *February 3d:* Medical Society of the State of New York (second day); Society of the Alumni of Bellevue Hospital; Harlem

Medical Association of the City of New York; Medical Microscopical Society of Brooklyn; Medical Society of the County of Richmond (Stapleton), N. Y.; Penobscot, Me., County Medical Society (Bangor); Bridgeport, Conn., Medical Association.

THURSDAY, *February 4th:* Medical Society of the State of New York (third day); New York Academy of Medicine; Brooklyn Surgical Society; Society of Physicians of the Village of Canandaigua, N. Y.; Boston Medico-psychological Association; Obstetrical Society of Philadelphia; United States Naval Medical Society (Washington).

FRIDAY, *February 5th:* Practitioners' Society of New York (private); Baltimore Clinical Society.

SATURDAY, *February 6th:* Clinical Society of the New York Post-graduate Medical School and Hospital; Manhattan Medical and Surgical Society (private); Miller's River, Mass., Medical Society.

Proceedings of Societies.

NEW YORK SURGICAL SOCIETY.

*Meeting of October 14, 1891.*

The President, Dr. CHARLES K. BRIDDON, in the Chair.

**Obstructing Cancer of the Rectum.**—Dr. WILLY MEYER presented a man sixty-one years old, upon whom he had operated for this trouble a year before. Bimanual palpation had revealed a large movable tumor obstructing the gut entirely. Inguinal colotomy was performed, and the gut was opened at once. Six weeks later the speaker did an exploratory laparotomy with the view of ascertaining whether the growth could be removed by this route, but he found the parietal peritonæum studded with the malignant growth, which had also spread over the mesocolon.\* He said that he now presented the patient, because he had been treating him for a prolonged period with the aniline dyes (pyocetanin), irrigating with a 1-to-1,000 solution, and methyl blue internally. He was aware that after the establishment of an artificial anus, as had been done in this case, these patients would often do well for a considerable period; still, he was inclined to attribute a good deal of the comparative well-being of this patient at present to the aniline treatment. The growth itself was unchanged in size, but the metastatic nodules were still slowly increasing. The man had remained in fair condition and had not lost weight during the past nine months.

**Excision of the Right Tonsil, the Pharynx, and the Tongue for Sarcoma.**—Dr. MEYER showed another patient, thirty-four years of age, upon whom he had recently operated, according to Miculiez's method, for a malignant invasion of the right tonsil, the tongue, and the pharynx. The patient had suffered excruciating pains, and though the speaker had feared that the operation would very much endanger the man's life, the patient had begged that it might be undertaken. Tracheotomy was first performed and the Trendelenburg tampon-cannula was introduced. Then an incision was made curving downward from the mastoid process to the chin, the flap was raised, and the glands, few and soft, were removed. Then the right external carotid artery was tied, also the ascending branch of the inferior maxillary. It was found necessary to remove the tonsil, with the pharynx of the right side, the epiglottis, and the whole tongue. The patient was narcotized through the tampon-cannula, and this instrument, with the blown-up bull, was kept in place forty-eight hours. It was then exchanged for an ordinary tracheal cannula. A soft-rubber catheter was passed through the wound into the œsophagus, and the patient fed

through it. The cannula was removed from the wound on the tenth day, and the man soon learned to swallow the stomach-tube. The patient, as would be seen, was now in good shape, complaining only of some shortness of breath. He could eat and swallow well, and was able to articulate distinctly enough to make himself understood.

**The Use of Wire and Pins in Ununited Fractures.**—Dr. L. A. STIMSON presented a man upon whom he had recently operated for ununited fracture of the thigh bone with considerable overlapping of the fragments. The speaker had cut down upon the parts and had taken off enough of the bone to permit of the fragments being brought into apposition by transverse section, placing the parts in a split so that the lower segment was supported by the upper. Satisfactory union had followed. He presented this patient in order to emphasize his opinion that the use of wire and pins in such cases was needless and probably detrimental, being likely to prevent rather than promote union.

**Fracture of the Head of the Radius.**—Dr. STIMSON also presented a patient who had come under his care with a fracture of the head of the radius. This was, the speaker said, quite a rare accident, some eighteen cases only having been reported, of which three had come under his own care. The injury had been produced in this case, as in most of the others, in the course of a backward dislocation of the bones of the forearm at the elbow. The patient, in trying to save a child from falling, had sustained an injury which had been diagnosed as a dislocation. He had remained under treatment for about two weeks, and had then come under the speaker's notice. Upon examination, there was found a prominence at the upper aspect of the elbow, and this seemed to be a portion of the head of the radius. An operation had verified this opinion. The specimen he presented as an example of a rare injury and to draw attention to the good results which had followed its removal. At the time of the operation the patient had lost the power of flexion and extension of the forearm, and almost entirely that of rotation. Motion was now very fair. The speaker would also draw attention to the beautiful appearance of the cicatrix, due to the use of Dr. Halsted's method of subcuticular suture.

**A Bullet in the Brain.**—Dr. J. A. WYETH presented a boy the full history of whose case had already been published. The youngster was shot at short range with a pistol in the hands of a playmate. The bullet entered the cranium and was never located. The boy was seen shortly after the injury and an incision was made admitting of the removal of pieces of bone which had been driven in upon the dura. The wound was then cleansed and an aseptic dressing applied. The boy had some slight symptoms of delirium for two or three days. He had been, however, kept exceedingly quiet and in the recumbent posture for a considerable time, and all the untoward symptoms had passed away. He had now been ten months out of bed, and seemed to be entirely well. The speaker had brought the patient to show the good results that might follow such an injury when no attempt was made to trace a foreign missile in the brain.

**Cancer of the Tongue.**—Dr. FRANK HARTLEY presented a patient who had been admitted into the Roosevelt Hospital on August 11th. The man was twenty-eight years old, married, and a farmer. His previous history gave nothing of interest. His present trouble, the patient thought, had begun three months before his admission. He had suffered mostly from a sore throat. He was examined by Dr. Beatty, and a diagnosis was then made of carcinoma involving the posterior third of the tongue and the adjoining portion of the anterior pillar of the fauces. The growth was distinctly circumscribed, hard, and only superficially ulcerated. The epiglottis was uninvolved and no glandular enlargement existed within the neck. The pos-

terior third of the right half of the tongue and a small part of the posterior third of the left half of the tongue were directly infiltrated. The man's general health was good. The heart and lungs were normal. There was no alcoholic habit. He smoked only moderately.

An operation was performed on August 18th, preceded by the usual antiseptics for the mouth, teeth, face, and neck. Tracheotomy was done and etherization carried on through the tube. A curved incision was made, five inches from the right angle of the mouth, downward and backward until the posterior part of the submaxillary triangle was entered. Hæmorrhage having been controlled, the inferior maxilla was divided at the site of the second molar tooth, after its extraction. The tongue was then divided parallel to, but midway between, the raphé and the left border. Both lingual arteries were tied as they entered the tongue from the hyoglossus muscle. The floor of the mouth on the right side and three fourths of the tongue were removed as far as the hyoid bone. The anterior pillar of the fauces and the tonsil on the right side were also removed, as the induration seemed to extend to them. An enlarged gland to the right of the pharyngeal wall and to the inner side of the ramus of the jaw was also taken away. The small portion of tongue remaining was sutured to the floor of the mouth. A drainage-tube was used in the lower angle of the wound, just below the division in the inferior maxilla. The inferior maxilla was held in position by catgut sutures through the bone. The skin was sutured with silk, and the mouth and pharynx were packed with iodoform gauze. The progress of the case had been as follows:

*August 19th.*—Rectal feeding every twenty-four hours. Temperature, 101°; pulse, 80.

*21st.*—Drainage-tube removed.

*22d.*—Tracheotomy-tube removed. Packing in the mouth and pharynx removed. Rectal feeding stopped. Stomach-tube used in feeding.

*26th.*—Primary union in the wounds. Peroxide of hydrogen used as a mouth wash; packing discontinued.

*29th.*—Use of the stomach-tube discontinued; fluid diet used.

*September 9th.*—Patient discharged; wounds healed; the teeth in good apposition.

An examination of the growth, made at the laboratory of the College of Physicians and Surgeons, had shown it to be a carcinoma.

**Cases of Gall-bladder Surgery.**—This was the title of a paper by Dr. ROBERT ABBE (See page 120.)

Dr. CHARLES MCBURNEY recalled the case reported by him this year in which the gall-stone was found lodged in the lower part of the common duct, in the hollow of the pancreas. The gall-bladder itself had entirely disappeared, doubtless owing to repeated attacks of inflammation. The stone, however, could be felt distinctly. It was impossible to reach the stone through incision in the side of the duct, and he had preferred to open the duodenum by vertical incision. He had then found the intestinal opening of the duct, split it upward for about an inch to the stone, and removed the latter through the intestine. The intestinal wound was then closed. The patient made an excellent recovery, and is now perfectly well. He would suggest as a useful method, where the duct was open above, that a sound should be passed from the gall-bladder down the duct in order to come as near the intestinal opening as possible, and so mark the position of the latter after the intestine was opened. In his case the opening was marked by the presence of a prominent ridge, two inches before it entered the intestine, becoming more and more marked as it passed down to the opening.

Dr. F. LANGE had had occasion several times to operate for obstruction of the common duct, both by stone and malignant growths at the head of the pancreas, and several of his cases had been brought before the society in former years and published. In a case in which he had performed colocoystomy for cancer of the pancreas the method of sewing the gall-bladder to the gut, which in this instance was the transverse colon, was by invaginating the gall-bladder into the gut. He had done this because the gall-bladder was extremely thin and because he had hoped that a valvular closure could be obtained. The patient had made a satisfactory recovery, but died six months later from progress of the cancerous growth. The general result of the operation, however, was not encouraging. The communication had diminished to an opening which would barely admit the passing of a probe. During life the appearance of gall in the stools had varied. At times it would disappear for a week or two and then come on again. He would therefore advise that this mode of operating should not be chosen. Perhaps it was better to invaginate the gall-bladder partly into itself, so that the edges of the incision could not come in contact again. It was an open question as to how much diminution would take place after this operation. In another case the malignant disease was complicated by the presence of stone. The patient was, however, in such a cholæmic condition that death had taken place from uncontrollable capillary hæmorrhage from within the gall-bladder, and probably from the liver, in the course of a few days. In both of these cases there were advanced liver changes.

Dr. LANGE also showed a number of gall-stones, removed from a lady on whom he had operated and who had malignant disease of the gall-bladder itself. The stones were of unusually large size. He had removed the stones, but had not thought that malignant disease existed. The wound, however, had not healed, but had kept secreting more and more, and luxuriant masses grew from the bottom of the gall-bladder. Microscopical examination had then determined the existence of large spindle-celled sarcoma, from which the patient eventually died, since radical operation did not seem advisable.

Dr. L. S. PILCHER cited a case in which he had operated last winter, when, at the time of the removal of some hundred calculi from the gall-bladder, the presence of a stone impacted in the common duct was appreciated, but the condition of the patient had then contra-indicated further interference. She had recovered from the operation, and before an opportunity could be made for again attacking the obstruction the calculus had passed spontaneously. He thought that sometimes, where it was necessary to leave the duct thus impacted, Nature might be looked to as likely to effect a cure. His patient had since completely recovered her health.

Dr. F. KAMMERER, referring to the last case cited by Dr. Abbe, thought that it was not often that so small a malignant tumor made such large deposits in the lung and liver. He had seen an interesting case of malignant disease lately. A woman had come to the hospital giving the history of biliary colic in former years. She was in a very low condition. Examination showed the existence of an enlarged liver, and below it was a large fluctuating tumor, the size of a child's head, reaching to the brim of the pelvis, giving the impression of a tumor of the kidney on bimanual palpation. As the patient had no jaundice, this case had presented some difficulties. He had punctured the liver several times and had got nothing. The patient had considerable rise of temperature and something had to be done. Puncture of the tumor itself drew away sero-purulent fluid. Operation had demonstrated that the tumor was an enormously distended gall-bladder. There was some ascites on incision. A large quantity of the sero-purulent fluid and some inspissated pus came

away when the gall-bladder was incised. When the fingers were introduced into its cavity large masses of *débris* and about forty gall-stones were found and extracted. There was a large perforation connecting with the liver, the distended bladder having become adherent to almost the entire lower surface of the liver, and the liver-tissue itself was much broken down. The patient had never rallied. Post-mortem examination had shown that the trouble was a malignant tumor of the gall-bladder. There were no metastatic deposits in the liver. The cancer was most likely a consecutive disease to the development of stone in the gall-bladder.

**Artificial Appliance after Removal of One Side of the Lower Jaw.**—Dr. McBURNEY, after calling attention to the great discomfort which resulted to patients subsequent to the removal of part of the lower jaw, from imperfect articulation of the teeth, cited a case in which he had done this operation for sarcoma and had called in other aid with a view to mechanically overcoming the subsequent difficulties. At the time of the operation he had had an interdental splint made, which was worn during the healing process. Afterward Dr. Albert Westlake had devised the apparatus, a model of which he exhibited. This device was still worn to-day by the patient with absolute comfort, keeping the teeth of the half jaw remaining in perfect articulation with those of the upper jaw and enabling the patient to masticate easily and perfectly. Absolutely no lateral displacement of the jaw existed to-day.

#### NEW YORK ACADEMY OF MEDICINE.

SECTION IN GENERAL SURGERY.

*Meeting of January 11, 1892.*

Dr. WILLIAM T. BULL in the Chair.

**Resection of the Rectum.**—Dr. WILLY MEYER presented a patient from whom he had removed a section of the rectum about four inches long on the 9th of October, 1891. The specimen was shown. The operation was performed in the kneelbow posture by Kraske's incision, the coccyx being resected. The rectum was then peeled away from its anterior attachments, the section made through healthy mucous membrane, and a piece of iodoform gauze passed upward into the gut. The gut was then brought down and secured. The bowels were opened on the tenth day. The patient now had control of feces and usually of gas, and had gained more than fifty pounds since the operation.

Dr. B. F. CURTIS showed a specimen representing an operation that he had recently performed for resection of the rectum and sigmoid flexure for carcinoma.

Dr. PARKER SYMS showed a specimen representing resection of the rectum for carcinoma. Allingham's operation had been performed, and it was believed that it had not been sufficiently thorough, as within two years a tumor was again felt in the rectum. In March, 1891, Kraske's operation was performed, and there had been no recurrence as yet. A preliminary colotomy was performed a few days prior to the Kraske operation, on account of the weakness of the patient. She now had partial control of the bowel.

Dr. A. SHUNK presented a specimen showing carcinoma of the rectum which he had recently removed. A left inguinal colotomy was first performed. Six weeks later the diseased rectum was removed through the opening in the left groin.

The CHAIRMAN showed a specimen of cancer of the rectum. The patient from whom it had been removed had apparently been cured by the operation.

**Intestinal Anastomosis.**—Dr. R. F. WEIR exhibited a patient who had been operated upon for an intestinal fistula which

had developed in connection with ventral hernia. The relations of the fistula to the intestine were ascertained by a careful dissection and separation of adherent intestines, the diseased portion was removed, and a lateral intestinal anastomosis was performed. A second patient was shown upon whom gastro-enterostomy had been performed for pyloric stenosis. A third was also shown who had been subjected to four abdominal operations for intestinal obstruction, the fourth, through a median incision, resulting in relief.

Dr. ROBERT ABBE presented a patient who had undergone four abdominal operations within a year. Three of them had been performed by Dr. A. F. Currier, the last one resulting in a persistent intestinal fistula. Dr. Abbe had operated for the relief of this, removing the segment of small intestine in which the fistula was located, and making a lateral anastomosis. The result had been entirely satisfactory, the patient being now in perfect health.

The CHAIRMAN showed a specimen illustrating gastro intestinal anastomosis. The operation had been performed for cancer of the pylorus. He also showed a specimen illustrating intestinal anastomosis. In this case an inguinal colotomy had been performed for cancer of the intestine. After the artificial anus had persisted three years Dupuytren's operation had been performed, but without satisfactory result. An intestinal anastomosis was then performed, and the patient lived two years in comfortable health. At the end of that period symptoms of intestinal obstruction appeared, and it was supposed to be due to contraction in the openings which had been made in the intestines. An abdominal section was performed, which showed that the obstruction was due to adhesive bands of the intestines. The operation had resulted fatally, and the autopsy had shown that contraction in the intestinal openings had not occurred to an extent sufficient to cause any interference with the intestinal function. The case was also instructive from the fact that five years and a half had elapsed since the cancerous growth had been removed, and there had been no recurrence.

Dr. ABBE read a paper narrating his recent experience with intestinal anastomosis.

Case I was that of the patient who had been exhibited.

Case II. In this case the symptoms of intestinal obstruction were pronounced. A left inguinal colotomy was performed without giving relief. This was followed by right inguinal colotomy, this by a median section at the outer border of the right rectus muscle, and this by a fourth section, which revealed a stricture twelve inches above the anus. A resection was made, and six months later carcinoma of the right ovary was diagnosed.

Case III illustrated lateral anastomosis performed on account of hernia of the abdominal wall with intestinal obstruction. The lateral anastomosis in this case was preferable to end-to-end suture of the segments of intestine, the latter procedure being impracticable on account of the difference in their diameters.

Case IV was one of Kraske's operation, in which the rectum had been resected six inches from the anus. Seven months later an inguinal colotomy had been necessary on account of recurrence of the disease.

Case V was one of strangulated right inguinal hernia with gangrene of the intestine. The gangrenous portion was excised, the opening in the gut extended an inch in each direction, and the opening closed by rows of sutures passed parallel to the transverse axis of the intestinal tube.

Case VI was one of cancer of the stomach. There was a decided tumor in the epigastrium with troublesome nausea, vomiting, and pain. The patient was very weak, but insisted upon an operation. After three days of stimulant treatment

the operation was performed. The stomach was found greatly dilated, and the tumor involved the pylorus and omentum. Gastro-enterostomy was performed, but the patient succumbed two hours after the completion of the operation.

Commenting upon these cases, which were all of recent date, the speaker remarked that almost all cases which called for the operation of intestinal anastomosis were cases in which the symptoms were severe and entailed much surgical shock. It had been urged that time was of the utmost importance in such operations, and, as a means of saving time and abbreviating the operations, various forms of plates had been devised. All such plates, whatever their construction or substance, were objectionable for one reason or another, and, after a considerable experience, the speaker was of the opinion that better results could be obtained without them, the intestinal openings being carefully apposed and secured to each other by sutures, and a double row of sutures being passed entirely around the portions which were brought in contact with each other. The intestinal openings should be four inches long; they might contract to half this length within six months, but they would be less likely to contract unduly if sutures alone were used than if dependence were placed upon intestinal plates. The speaker was not entirely satisfied that the experiments in anastomosis of the intestines of dogs could be depended upon as analogous to the work which was required upon the human intestine. The tolerance of dogs was greater than that of human beings; their tissues also presented different conditions. In many of the cases in which intestinal anastomosis was decided upon the patient should be prepared by a preliminary colotomy.

Dr. J. A. WYETH believed that intestinal anastomosis could not be regarded in any sense as a simple operation, and thought that the prognosis in the majority of cases in which it was performed would be bad. He was not in favor of lateral anastomosis in any case in which terminal anastomosis was admissible.

Dr. B. F. CURTIS thought that if lateral anastomosis was to be performed the method by suture alone was preferable to that by plates. If the circular suture (end-to-end operation) could be performed there would be less contraction of the lumen of the gut than by the lateral method, but the former operation was the more difficult. Concerning the criticism made upon intestinal surgery in dogs, it was true that dogs resisted purulent infection better than human beings, but he had not found that they resisted faecal infection any more successfully.

Dr. J. D. BRYANT emphasized the necessity of promptness in operating in cases of intestinal disease in which anastomosis was necessary. Delay weakened the condition of the tissues and so rendered them less suitable for resistance when the operation was performed.

Dr. WEIR remarked that the statistics of the lateral intestinal operation were thus far much better than those of the circular operation. Therefore we were not yet in a position to discard the former method.

Dr. F. KAMMERER expressed a preference for the method by sutures alone over that in which rings or plates were used.

Dr. MEYER quoted the statements of Kraske, Bramann, and Schede as preferring the circular suture to any other method after resection of the rectum. He also spoke of the necessity of protecting the peritoneal cavity from soiling when removing the rectum.

Dr. SYMS had found the rings ineffectual to prevent extravasation of faeces after lateral anastomosis. He had lost a patient after such an accident.

Dr. R. H. M. DAWBAEN adhered to his opinion that plates were more useful in intestinal anastomosis than sutures alone. With plates one was far less likely to pierce the mucous mem-

brane of the intestine than with sutures alone; hence there was less danger of faecal infection. He also believed in the advantage of the few minutes of time which could be saved when plates were used. Abbe's catgut rings were believed to be an improvement upon Senn's bone plates, but the potato plates which had been devised by the speaker would retain their position longer than the catgut rings.

## Reports on the Progress of Medicine.

### NEUROLOGY.

**Nervous Complications of Gonorrhœa.**—In the *Gazette des hôpitaux* for September 5, 1891, Dr. Paul Raymond states at length the complications of gonorrhœa. They are not unlike those induced by other forms of infectious disease. Charvot, in his article on sciatica, says that two predisposing pathological factors of this disease are found in pelvic inflammations among women and gonorrhœa in men. When due to gonorrhœa, sciatic inflammation rarely appears during the first week, but is delayed till the second or third week. The onset is sudden, almost instantaneous. The early symptoms often come on in a night, and their extreme limit of severity may be reached in twenty-four hours, relative calm being established in four or five days. Then the neuralgia disappears, or remains stationary for a time, worse at night, and always most intense about the exit of the sciatic nerve. The pain travels down the thigh, but rarely beyond the popliteal space. There is also a erural neuralgia of similar onset and origin. These conditions coincide with the degree of articular manifestation in gonorrhœa, both being complications or extensions of an infectious process. A double sciatica suggests the involvement of the spinal cord—a meningo-myelitis. Meningeal inflammation of the cord in no wise differs clinically from other infectious forms of myelitis, from the erysipelatous, from that due to variola or typhoid fever. When due to gonorrhœa, it usually lasts from a fortnight to six months, and quite exceptionally over two years. Death sometimes occurs. Reflex paralysis due to joint trouble gives about the same symptoms as a true myelitis, without organic lesion. There are also muscular atrophies following gonorrhœa that do not appear to be consecutive to the joint lesions. Abnormalities of special sense appear as complications of gonorrhœa. Amblyopia may accompany multiple arthropathies and last several days. Optic neuritis of similar origin has been noted, and also severe headache and deafness. The skin does not escape. A gonorrhœal erythema sometimes appears that is a true angeioneurosis. This is a morbid process quite distinct from eruptions due to local applications, such as balsam of Peru, which are frequently seen during the treatment of gonorrhœa. The cutaneous complications of nervous origin are symmetrical and have more the appearance of congestion than of true inflammation.

**The Diagnosis of Anæsthetic Leprosy and Syringomyelia.**—In the paper contained in the *Revue de médecine* for September 10, 1891, Dr. Marestang arrives at the following conclusions to the effect that syringomyelia and anæsthetic leprosy are distinct entities, thus proved by pathological anatomy. Syringomyelia is based upon a medullary process, of gliomatous nature most frequently, while anæsthetic leprosy is the outcome of a specific neuritis. There are certain clinical differences:

#### *Syringomyelia.*

Disassociation of sensory disturbances.

Integrity of superficial muscles of the face.

Absence of discolorations on the skin.

Hair unaffected.

Deviations of the spine.

In leprosy there is spontaneous resorption of the phalanges, profound alteration in the nails, partial or complete loss of hair, and the

#### *Anæsthetic Leprosy.*

Abolition of the sense of touch.

Atrophy and paresis of superficial muscles of the face.

Thickening and nodular swelling of nerves.

Discolorations (painless) upon the body.

presence of Hensen's bacillus in the portions of tissue that are ulcerated.

**Neurasthenia and its Mental Symptoms.**—In the *Medical Communications of the Massachusetts Medical Society*, vol. xv, No. 2, 1891, appears in full Dr. Edward Cowley's exhaustive paper with the foregoing title. Neurasthenia is one of the most frequent and important of nervous diseases. Its mental symptoms afford significant indications for diagnosis, prophylaxis, and treatment. Depression, weakened mental control, and irritability are signs of the characteristic mental weakness. Insanity, in its functional and curable forms, is always weakness, and its study is useful in relation to neurasthenia, because they have a common origin. In normal fatigue, toxic products of exercise are formed in nerve and muscular tissues. From this and other sources toxic elements may accumulate in the blood and tissues. In pathological fatigue these contribute to local or general inanition or auto-infection. Visible changes in nerve cells that attend normal fatigue go to support the inference of a molecular and chemical variation, in pathological fatigue, that manifests itself as a condition of exhausted or changed nutritional power. To the ætiology and pathology of neurasthenia they bear a direct relation. Habit, diathesis, idiosyncrasy, have an important influence in causing "dispositions to repeat organic processes," whether normal or abnormal. The analysis of normal and pathological fatigue shows that mental symptoms in the latter may be easily recognized. They correspond with the physical events in neurasthenia. The phenomena, so far as they go, are in unison with the like conditions of melancholia. The symptoms are objective and subjective, mainly the latter, which include the mental symptoms. There is mental depression and a sense of ill-being; diminished power of voluntary attention and mental control; introspection and worry, with attention acting in its attracted form; and changes in the "sense of body"—irritability and hyperæsthesia, languor and anæsthesia. In consequence, two conditions of clinical importance become prominent. These are morning weariness and anæsthesia of the sense of fatigue. Neurasthenia, then, is a morbid condition of the nervous system, and its underlying characteristics are excessive weakness and irritability or languor, with mental depression and weakened attention. It may be regarded as the initial term of many nervous disorders having a varied ætiology. The treatment logically includes elimination, rest, exercise, massage, and the promotion of sleep. The mental indications and other subjective symptoms, being the earliest and most significant always, are the best guides to treatment. This must be suited to the different stages of neurasthenia, to the conditions of first effects and after-effects, and to the special type that the patient represents.

**Facial Neuralgia and Ear Troubles.**—A most interesting series of observations, recorded by Dr. Gellé, upon the condition of the ear in various forms of nervous disease has appeared in recent issues of the *Progrès médical*. The coexistence of pain in the ear and neuralgia upon the same side of the face was found in twenty-two cases of facial neuralgia. Often facial neuralgia starting from different points is symptomatic of acute inflammation of the ear, or of new inflammatory attacks set up on some former diathetic otorrhœa. The facial pain in this case precedes by several days the otic or periotic complication. At times, in spite of frequent attacks and intense otalgia, the ear itself remains sound. In certain instances the attacks bear a close relation to a simple or diathetic inflammatory condition at the level of the orifice of the Eustachian tube. In three cases examined, syphilis proved to be the cause of the unilateral ear difficulty, one of the patients presenting severe otalgia without lesion for some time before the appearance of a subacute otitis resulting in suppuration, secondary symptoms appearing only after the ear trouble. There is a history of facial neuralgia in nearly all cases of chronic deafness. It is also a frequent premonitory symptom of facial paralysis, and accompanies vertigo *ab auro lesa* and hyperæusia. The cases cited demonstrate a close relationship between facial neuralgia, acute otitis, and facial hemiplegia.

**Guarana in Migraine.**—The *Journal de médecine* for October 18, 1891, quoting from Pemberton Peake, recommends the following method of warding off or ameliorating an attack of migraine: When prodromes appear—restriction of the visual field, ringing in the ears, etc.—work must cease. The patient is to take twenty or thirty grains of guarana in a little broth, go to bed, and try to sleep. When the characteristic

headache begins, a good-sized cup of tea is in order. A little reading or conversation will help banish the depression that the pain causes. This plan of treatment shortens the attack.

**Facial Paralysis due to Rupture of the Ear-drum.**—In the *Journal de médecine de Paris* Dr. Delobel records a case of this kind. The patient was thrown from a carriage, falling upon the left side of the head. There was a cut about the root of the nose, and bleeding from the nose and ear. There was no loss of consciousness, will, or of movement; no vertigo, no evidence of fracture. The patient complained of great pain, noises, and deafness in the left ear. This prevented his hearing a watch applied to the ear, though the sounds were heard distinctly when it rested upon the forehead or was put into the mouth. Eleven days after the accident complete left-sided facial hemiplegia was present. There were disturbances of taste and diminution of sight. Electricity and strychnine were the remedies used. In about two weeks a slight improvement was noticed. All paralysis disappeared by slow degrees, and in time the sense of taste returned. Symptoms pointing to some deep-seated lesion of the seventh pair of nerves, as loss of taste and of faradic response in muscles supplied by them, caused the author to regret that he did not use subcutaneous injections of pilocarpine, as suggested by Strauss, to settle at once the question of profound lesion by the absence or delay of sweat on the affected side or its simultaneous presence on both sides.

**Paraplegia of Syphilitic Origin.**—The *Annales de dermatologie et de syphiligraphie* for October, 1891, contain a report of this condition, based upon seventy-one cases, by Dr. Pierre Bouillocke. The facts appear in the form of brief *résumés*, the chief points being the earlier existence of syphilis, the age at which paraplegia appeared, and its course, nature, and duration. Syphilitic myelopathy alone is rare—found only seventy seven times in a given number of cases in which cerebro-spinal syphilis existed four hundred and sixteen times. At what age of the disease does paraplegia make its appearance? Among the cases under consideration evidences of paraplegia existed during the first year of infection in eight cases, in the second year in eighteen, in the third year in ten, in the fourth also in ten, from the fifth to the tenth year in seventeen, and between the tenth and the twenty-second year in eight. Therefore, in sixty-two cases of paraplegia out of every hundred the onset has been during the first four years following the initial lesion. Late syphilitic myelitis is comparatively rare. Myelitis of syphilitic origin that develops rapidly within a few weeks or two or three months is most unfavorable as regards prognosis. Chronic diffuse myelitis is seldom fatal, and it is not often completely cured. Vesical troubles remain after nearly all the signs of paraplegia have disappeared. Weakness of the legs, difficulty in walking and standing upright for any length of time, a certain degree of contracture in severe cases, are some of the after-effects more or less permanent.

**The Neuroses of Development.**—Dr. T. S. Clouston's admirable lectures on this subject that have appeared in various issues of the *Edinburgh Medical Journal* during the year end in the August number with a few considerations in regard to prevention of the neuroses of development. Heredity is a question of degree and intensity in each case. Fortunately, in most instances it needs an exciting cause to develop the diseases which are its outcome. There are one or two general principles safe to follow as making for prevention. Build up bone and fat and muscle, especially fat, by every known means during periods of growth and development. Make fresh air the breath of life to the young. Develop lower centers rather than higher ones when there is poor heredity. Avoid, if possible, alcohol and nervine stimulants. Do not cultivate, rather restrain, the imaginative and artistic faculties and ready sensitiveness and idealisms generally in cases where such tend to appear too early and too keenly. They will be rooted on a better brain and body basis if they come later. Cultivate and insist on method and order in all things. The weakly neurotics are always disorderly, unbusinesslike, and unsystematic. Fat, self-control, and order are the three most important conditions for them to aim at and develop.

**Attacks of Tremor among Epileptics.**—Dr. Feré notes in the *Revue de médecine* for June 10, 1891, the different aspects of tremor among epileptics. It may be merely an episode in the classic epileptic seizure, or the only symptom of a paroxysm, with loss of consciousness. Some-

times tremor lasts for hours or days, either general or local. It is usually rapid, especially in the hand, the oscillations ranging from seven to ten a second.

**The Pathology of Ophthalmoplegia.**—This is the subject of an interesting paper by Dr. J. W. Collins, of London, and Dr. L. Wilde, of Durham, England, in the *American Journal of the Medical Sciences* for November, 1891. Owing to the complexity of the structures concerned, post-mortem examinations have been of comparatively slight value. The site and nature of the lesion to which the group of oculo-motor palsies is due have been mooted questions. In no other situation are there opportunities for a small lesion to affect so many cranial nerves as in the cavernous sinus. Putting aside the rather obscure ocular palsies of cortical origin, the floor of the aqueduct of Sylvius and fourth ventricle and the walls of the cavernous sinus would be the most favorable site for small lesions to bring about extensive results. In the former, such lesions would be mostly nuclear, in the latter necessarily neural. The authors introduce the following scheme:

#### OPHTHALMOPLÉGIA.

##### I. Cerebral.—

- |                         |  |
|-------------------------|--|
|                         | } Conjugate deviation.   |
| (a) Cortical.           |  |
|                         | } Hemiptosis (?).  |
|                         |  |
| (b) Cortico-peduncular. |  |
| (c) Nuclear.            | } 1. Cycloplegia. } "Ophthalmoplegia interna."<br>} 2. Iridoplegia. }<br>} 3. Palsy of the extra-ocular muscles; ptosis. |
| Third nerve.            |  |
| Fourth nerve.           |  |
| Sixth nerve.            | 4. Palsy of the superior oblique.  |
|                         | 5. Palsy of the external rectus.   |

##### (d) Radicular (and ? commissural).

##### II. Basal.—(a) Region of pons.

- |     |     |                     |
|-----|-----|---------------------|
| (b) | " " | peduncles.          |
| (c) | " " | cavernous sinus.    |
| (d) | " " | sphenoidal fissure. |

##### III. Orbital (including peripheral).

Ophthalmoplegia of cortical or cortico-peduncular origin is usually conjugate, not unilateral. The only exception to this rule, apparently, is that of ptosis occurring exclusively upon the side opposite to that of the cerebral lesion (Landouzy). Observations by the authors of 120 cases show that some evidences of syphilis were found in 33 per cent.; of the whole number, 65 per cent. were men; from twenty to forty years of age were the periods of its most active manifestations; and the condition was unilateral in 61 cases. In 65 of the patients in which external ocular muscles were affected, there was also some disorder of intra-ocular muscles. In 29 of the 65 both iris and ciliary muscle were involved. Special attention must be directed to the mode of linking of extra-ocular palsies with cycloplegia and iridoplegia, respectively, as bearing upon the work of Henser and Volker, and of Kohler and Pick. In the 34 cases in which only one of the two—viz., iris or ciliary—was affected, plus extra-ocular palsy, in no less than 31 the iris and not the ciliary presented abnormality. In only three, therefore, was the ciliary alone affected. If it be true that the centers for ciliary, iris, and extra-ocular muscles are arranged in the foregoing order, tandem fashion, on the floor of the aqueduct, the connection of these ocular palsies is at once apparent. In 116 cases, analysis in regard to distribution of the palsy according to nerves involved showed an implication of the third nerve alone in 47 instances. In 42, the third, fourth, and sixth were affected in company; in 11, the sixth only; in 8, the third and fourth together; in 4, the third and sixth; in 2, the fourth and sixth; and in 2, the fourth alone. Of the 92 cases out of the 120 in which the result is noted, 53 improved under treatment, 26 completely recovering. In 15 there was no improvement, in 2 the disease was progressive, and in 22 fatal. Under ten years of age 50 per cent. died; over ten, 23 per cent.

**A Case of Acromegaly.**—This is reported in detail in the *Revue de médecine* for September 10, 1891, by Dr. Spillmann and Dr. Haus-halter. The tables of measurements are particularly interesting. The patient, a *religieuse*, fifty-two years old, noticed the onset of her present condition at the age of forty, up to which time she always enjoyed robust health. Menstruation then ceased suddenly, to be immediately followed by a gradual enlargement of face, hands, and feet. The skin

thickened by degrees and the back became arched. The characteristic ugliness of acromegaly is reproduced in the cuts illustrating the report. The patient is cheerful, without headache or any sensory trouble, and with mind unaffected. Gloves are not manufactured sufficiently large for the hand, and men's shoes of enormous width and length are the only ones this *religiense* can wear. The ocular troubles consist of marked amblyopia on one side and almost complete amaurosis on the other. There is no sensitiveness to cold, but constant complaint of heat. The skin is oily and frequently covered with profuse perspiration.

**The Brain in Microcephaly.**—Dr. Giacomo has recently made public his observations upon this subject, of which the following is a *résumé*: The morbid process causing microcephaly is essentially one of the central nervous system, and the deformity of the skull results from want of development of the brain. There is no microcephaly that is primarily osteal. It is always neural. The condition is not confined to the brain alone. There is also micromyelia. The nervous system in microcephaly presents no pathological alterations that could be produced by arrest of development. The brains all belong to the human type, varying according to the period of embryonic life wherein arrest of development took place, and ranging in degree from one below the normal adult brain to the verge of anencephaly. The formation of the cortex in extreme cases, aside from the evident arrest of development, bears much resemblance to that of certain animals and may be considered an example of atavism to the evolutionists, for this formation has never existed during the historical period of the human race.

**Synopsis of Opium Inebriety.**—In the *Journal of Mental and Nervous Disease*, June, 1891, there is a paper with the foregoing title. Morphomaniacs include literary men, mathematicians, and scientists. Medical men are more exposed to the formation of the habit than any other class. They have a seemingly reasonable excuse, knowing the speedy effect of morphine that permits a return to work. In time the will is paralyzed and personality destroyed. Molecular changes are brought about and a neurosis is produced. Mental faculties are the ones that suffer first from the use of opium. There are marked depression of spirits, hallucinations, especially of sight, and morbid fears. Sensation is usually impaired or perverted. There is a wan complexion, greasy skin, a vacant look, listlessness, loss of appetite, and obstinate constipation. Upon the withdrawal of the drug there is diarrhoea. If this does not occur, it is safe to suspect that the patient still continues the use of opium in some secret fashion. There are several plans of treatment. The noted German, Dr. Livenstein, stops all morphine at once without regard to length of habit or dose. This entails much mental and physical suffering and the risk of suicide. Collapse is threatened. Against this plan Dr. J. B. Mattison, of Brooklyn, expresses himself with much emphasis and holds that no man is warranted in subjecting his patient to such horrible torture. The dread of such an ordeal as described by others keeps many in the continued toils of the morphine habit. The rapid but not abrupt withdrawal of opium is what Dr. Mattison advocates. A certain amount of control of reflex irritation may be obtained by bromide of sodium in large doses for four or six days. The maximum sedative effect of the bromide should be secured by the time the maximum nervous disturbance is expected or brought about by withdrawal of the opium. But even this plan causes much suffering. The gradual method seems more rational. The only reasonable hope for cure at all is in the wise care of a specialist familiar with all the exigencies that may arise. A collapsed condition is best met by stimulants, ammonia or alcohol. Delirium can be warded off by coca, chloral, and bromides. For vomiting, stop all solid food, give hot beef extract, hot milk, and beef peptoids in liquid form; and as remedies ammonii ar. spir., bismuth subnit. To overcome diarrhoea, first use an emulsion of castor oil with brandy; then give bismuth subnitrate and zinc sulphocarbolate. Treat pains in the legs by hot foot-baths, massage, and friction. In the event of apparent sleeplessness, be sure, first, that the patient is not shamming, and then administer full doses of bromide, sulphonal, and sometimes valerianate of zinc in the form of elixir. Codeine can be given to allay pain as safely as any opiate and without great danger of its use growing into a habit. In anæmic conditions, iron and strychnine are indicated. In notable depression or long-lasting prostration, alcoholic stimulants are required. Restlessness and insomnia may be warded off

by a hot bath before retiring. Electricity, especially the electric bath, will in most cases tranquillize the system. Mental quiet is a positive essential. Cheerful surroundings, amusement, and pleasant society are necessary. If the patient uses the hypodermic syringe, this should be instantly discarded and all opium given by the mouth. The physician should take complete possession of his charge, and be to him a constant, kind adviser and moral support.

Miscellany.

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. Walter Wyman, Surgeon-General of the Marine-Hospital Service, and published in the Abstract of Sanitary Reports for January 22d:

CITIES.	Week ending—	Population, U. S. Census of 1880.	Total deaths from all causes.	DEATHS FROM											
				Phtisis pulmonals.	Yellow fever.	Small-pox.	Variceloid.	Varicella.	Typhus fever.	Enteric fever.	Scarlet fever.	Diphtheria.	Measles.	Whooping-cough.	
New York, N. Y. ....	Jan. 16.	1,515,301	907	110							4	41	39	12	7

**The Treatment of Influenza.**—The following, except for a few verbal changes, appeared as an editorial in the *Boston Medical and Surgical Journal* for January 21st:

In the prophylaxis of influenza it must be remembered that the disease is a something (germ or other morbid factor) plus, not infrequently, a severe cold. A catarrh or cold is a mechanical congestion of the naso-pharyngeal mucous membrane due to exposure to alternating temperatures, not necessarily accompanied by fever or any constitutional disturbance. This congested mucous surface furnishes a favorable nidus for the influenza germ as well as for the germs of ordinary suppuration. The germs or their ptomaines find entrance into the blood and produce the rigors and other constitutional symptoms. The main prophylactic indication, then, would be to avoid, as far as possible, the causes of ordinary colds. When once the congestion is established, means should be taken to prevent this extending, and to destroy any germs that have effected lodgment on the congested membrane. Here the use of diaphoretics (a warm bath, a vapor bath, heaters, liquor ammonii acetatis, jaborandi, Dover's powder—the patient being in bed) may be salutary; the symptoms of prostration are to be treated by abundant stimulants. The menthol spray, or eucalyptus inhalations, stimulate the local circulation, and are perhaps germicides. The eucalyptus may be inhaled from a handkerchief, and a two- to five-per-cent. [solution?] of menthol in some form of liquid vaseline be injected into the nostrils in chronic catarrh.

There is no special treatment for the bronchitis of influenza. The acuteness of the attack, the oppression, the teasing, dry cough, the scanty expectoration of the first stage, indicate the need of expectorants and salines, whilst the prostration indicates the disadvantage of their administration. Ten drops of wine of ipecac, one drop of tincture of aconite, five grains of nitrate of potassium in a dessertspoonful of liquor ammonii acetatis, constitute a convenient mixture for this stage of the disease; the dose may be given every two hours during both day and night, or the tincture of lobelia inflata in five-minim doses may be substituted for the ipecacuanha wine. Citrate of potassium in thirty-grain doses with lemon juice and syrup is a favorite combination, making a mixture which is very pleasant to take. No one will question the beneficial effects of hot fomentations and cataplasms to the chest, especially when there is pain and dyspnoea. The old custom of giving an emetic at the onset of a severe bronchial attack has gone out of fashion, still there are times when nothing will so speedily relax the tightened bronchi, allay the element of spasm, and promote expectoration, as a full dose of ipecac or turpeth mineral. The latter emetic is especially applicable to children with abundance of subcrepitan râles all over the chest, dyspnoea, and other symptoms of capillary bronchitis.

When expectoration has begun (and in influenza it sometimes does not begin at all) there is probably no better expectorant than carbonate or chloride of ammonium. The latter, if rubbed up with extract of licorice and taken in emulsion, in water or in syrup, is not especially disagreeable to the taste. The aromatic spirits of ammonia may be given in syrup of Tolu or syrup of senega, and often no other expectorant will be needed. Marotte has recently published a paper in which he recommends, in order to oppose the pulmonary manifestations of *la grippe*, the employment of chloride of ammonium in doses amounting to two or three grammes daily. He would give the salt in capsules or cachets, the dose being fifty centigrammes.\*

As the adynamic symptoms are always marked, a supporting treatment should be instituted from the first, and alcoholic stimulants are frequently indicated. A tablespoonful of whisky in a glass of milk is a favorite combination with many. Or the milk is given in teacupfuls every two hours, and is alternated with a glass of grog or champagne. The alcohol often seems materially to aid expectoration, besides combating restlessness and insomnia. It is especially in broncho-pulmonary cases, complicated with weak heart and pulse, that alcohol is a necessity. Physicians doubtless do not sufficiently utilize the stimulating and supporting effects of strong coffee, which may often be allowed to advantage in influenza *ad libitum*.

Where the cardiac enfeeblement is very marked there can be no question as to the benefits of digitalis, strophanthus, caffeine, and sometimes of nitroglycerin. In the pneumonia and broncho-pneumonia of influenza the leading indication is often to support the struggling heart, and digitalis may be given here with often happy effects. An eligible form is the infusion, of which a teaspoonful may be given every two hours for a day or two; then strophanthus or caffeine may be substituted for the digitalis.

Many practitioners have great faith in sulphate of quinine, both as an abortive means in the early stages (abridging duration of the attack), and as a supporting agent all through the sickness. By general consent, however, quinine has of late been relegated to a secondary and subordinate place in the therapeutics of this and other affections, being given in rather small doses and for its tonic effect.

For the nervous symptoms of influenza—the headache, the backache, the pains in the limbs, the restlessness and insomnia, etc.—there seems to be nothing so good as acetanilide or phenacetin, and no medicines are more generally prescribed. Just how these medicines act is not yet known, but they certainly have a marked action in allaying the rheumatoid and neuralgic pains of influenza, and they also combat the fever element and relieve the insomnia. A recent writer in the *Lancet* even affirms that acetanilide is enervative of the bronchitis, destroying the micro-organisms that pervade the mucous membrane and the sputum; and that he has found it to cause the cough to disappear. Other practitioners may not have seen the same results, but there is abundant

testimony that phenacetin and acetanilide are invaluable and safe medicaments in influenza. The former may be given in ten- and the latter in five-grain doses every two hours until the muscular or neuralgic pains cease; two or three doses generally prove sufficient. Some prefer to give stimulant with these drugs, as it hastens their action and counteracts any depressing effects. When the muscular pains are obstinate, salol (five grains) or salicylate of sodium (fifteen grains) have been recommended.

A capital point in the treatment is to watch the patient, that he be not allowed to go out too soon, for cases are not rare where, after a light attack, exposure to cold has been followed by fatal pneumonia.

We can but just allude to MacLagan's treatment of influenza by salicin in large doses. This writer reports a series of cases which, he maintains, go to show that salicin in doses of twenty grains every hour for five or six hours, then every two hours for a day, "arrests the course of the disease as effectually as it does that of acute rheumatism when given in the same manner." In all his reported cases the cure was rapid, "the temperature falling to the normal, and convalescence commencing in all within twenty-four and in most within twelve hours of the commencement of the treatment."

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. A CONTRIBUTION TO  
THE SURGERY OF THE ŒSOPHAGUS.\*

By ARPAD G. GERSTER, M. D.

In the summer of the year 1878 a Polish Hebrew peddler, hastily swallowing a piece of beef stew, was suddenly choked by a hard body, which he felt entering and become arrested in his gullet. The initial dyspnœa disappeared, but constant pain was felt in the œsophagus, which was acutely augmented by efforts at deglutition. Only liquids could be swallowed.

The medical man whose aid was sought for the relief of the sufferer first attempted to ram the foreign body down into the stomach. The pain felt by the patient was so intense that these attempts had to be given up. Emetics were then administered, and when these had failed to bring up the foreign body, large doses of castor oil were given by mouth and *per rectum*. Thus five days passed by. On the sixth day after the accident the patient was examined by the writer of this paper. Considerable fever and an anxious expression were observed, and dysphagia and a constant pain low down in the neck were complained of. Liquids could be swallowed with difficulty, solids not at all. The œsophageal sound was arrested at a distance of nine inches from the lower incisors by a hard, immovable body, which did not permit its passage lower down. A long curved œsophageal forceps was passed, and it was very easy to grasp the body, but whenever an effort was made to dislodge it, the instrument slipped off. Evidently the body was so firmly impacted that any endo-œsophageal methods at extraction were hopeless; hence immediate œsophagotomy was earnestly recommended. The patient was admitted to one of our city hospitals, where he lay unattended for five days more. On the sixth, external œsophagotomy was performed, the patient then being very feeble from high fever and the lack of nourishment. The gullet was opened without much difficulty, but the extraction of the foreign body was accomplished even then with very much trouble, on account of its size and shape. It was a triangular and equilateral piece of bone, each side being about an inch and three quarters long, and its thickness about half an inch. The bone emitted a fetid odor, and some blood escaped from the gullet after its extraction. The external wound was left partially open.

The fever from which the patient had suffered before the operation did not abate: the entire wound became septic, ill-smelling, and coated with a yellowish deposit, and five days after the extraction, in the night, he bled to death from the internal jugular vein, the wall of which had sloughed extensively. The slough was detached in the night and, before aid could be summoned, the patient had died.

The lesson drawn from this case was too drastic to be forgotten. It taught the perniciousness of delay in extracting impacted foreign bodies from the œsophagus, and the uselessness of a late operation.

Here the foreign body was very large, very unfavorable for a safe passage, and its sharply projecting angles were extremely dangerous during attempts at dislodgment and extraction. But is the presence of a less angular body—such as, for instance, a coin impacted in the œsophagus—free from danger?

Let the following history answer this question:

Frederick P., a year old, exhibited symptoms of an intense tracheal stenosis, principally *obstructing expiration*. The patient came under the care of the writer on March 6, 1886, by the kindness of Dr. Boldt. Tracheotomy was done at once at the German Hospital without relief. On March 10th the child died of pneumonia. On autopsy, a brass trousers-button was found imbedded in old cicatricial tissue between the trachea and œsophagus, midway between the cricoid cartilage and the bifurcation. An open communication existed between the two tubes. The button was held in place by a rim of cicatricial tissue in the œsophagus, its free lower margin projecting downward into the lumen of the trachea like a valve. Thus, inspiration found no impediment, but on expiration the valve was raised and extreme expiration stenosis was the result. The parents remembered that weeks before the child had swallowed a button, but, no trouble being noticed then, the matter had been forgotten.

The study of an excellent paper by George Fischer,\* in which the histories of eighty cases of œsophagotomy for impacted foreign bodies are collated, will show that, though the shape or size of the impacted body is of great importance as to the ultimate issue, the length of time during which the impaction remains unrelieved is of much greater moment. Ulceration by pressure will destroy the integrity of the mucous lining, and thus a portal for the entrance of infectious matter is opened. Phlegmonous processes accompanied by sloughing will lead to perforation into adjoining organs or closed cavities—such as the trachea, the pleura and lungs, the mediastinum, the large vessels—almost each of these complications having a fatal significance.

Twice the writer has been obliged to practice laryngo-fissure on account of extensive perichondritis caused by the penetration of a foreign body from the œsophagus. One of the histories is as follows:

Julius M., a peddler, aged thirty-nine. The previous history pointed at the lodgment of a foreign body in the œsophagus, with dysphagia, which disappeared spontaneously. Gradually dyspnœa supervened. The laryngoscope demonstrated the presence of a small irregular tumor in the larynx, the size of which did not seem to explain the intense dyspnœa. Tracheotomy was done December 18, 1886, at Mt. Sinai Hospital. On incising the trachea above the thyroid body, a granulating but dense mass, occupying the posterior and lateral aspects of the larynx just below the vocal cords, was exposed. Surrounded by this mass was found the point of a wooden skewer, an inch in length, its ends being imbedded diagonally in the tissues between the larynx and œsophagus. No open communication with the latter organ could be found by probing. The cricoid cartilage was divided, the body was extracted, and the granuloma was excised. On December 27th the tracheal tube was removed. The outer wound healed promptly, but the old dyspnœa again reappeared, so that on January 27, 1887, laryngo-fissure was performed. Moderate return of the new growth was found about the defect of the mucous membrane in which the wooden splinter had been imbedded. The probe was introduced into the aperture and penetrated downward and backward to the distance of three fourths of an inch, thin pus exuding from the sinus. Intense swelling and hyperæmia of the entire mucous membrane and submucous tissue of the larynx and adjoining trachea were noted. In view

\* Read before the New York Surgical Society, November 11, 1891.

\* *Deutsche Zeitschrift für Chirurgie*, vol. xxv, p. 565.

of the perichondritis a tracheal tube was left inserted in the wound. Subsequently during the writer's absence from town various attempts were made at wearing an O'Dwyer tube with a view to curing the stenosis, but these efforts remained futile. In June some cartilage was expelled and the patient recovered.

The second case referred to was almost identical with the one just related. The patient was operated on at Mt. Sinai Hospital in the winter of 1890. A wooden splinter had penetrated the posterior wall of the trachea at its junction with the larynx, and had caused necrosis of a considerable portion of the thyroid cartilage. After the expulsion of this the dyspnoea was abated and the tracheal tube could be dispensed with. But a rebellious tracheal fistula persisted at the site of the tracheotomy wound and was successfully closed by a plastic operation identical with that devised by Szymanowsky for the closure of urethral fistulæ.

In reviewing the vast material presented by George Fischer, we unhesitatingly come to the conclusion that, if a foreign body becomes lodged in the œsophagus and can not be displaced downward into the stomach or extracted without the employment of much force, it is imperative to perform external œsophagotomy at once. With the exception of cases in which a goitre or cervical tumor impedes the otherwise simple steps of the operation, the procedure as now practiced is comparatively safe, its rate of mortality for all cases, recent and old, good and bad, being computed by Fischer as twenty per cent. The conditions are parallel to those existing in strangulated hernia. *An early operation is safe; a late one dangerous and very often useless.* Delay extending over twenty-four hours is never justified, and if at the end of this period extraction by bloodless processes is not easy, the gullet ought to be cut at once.

Tedious and often-repeated attempts at dislodgment, in a case where impaction has been present for more than twenty-four hours, are apt to be more dangerous than œsophagotomy. The patient's general condition is usually bad from fever and starvation, and the depressing effects of the manipulations in the fauces and œsophagus, productive of nausea and vomiting, are not to be slighted. Finally, the further injuring of the mucous membrane in the presence of septic ulcerative processes or sloughing, and the probability of causing *traumatic* perforation, are to be well weighed.

As regards the technique of œsophagotomy, the following points have to be observed: The incision should be ample, to permit comfortable operating without the employment of much traction and bruising of the organs exposed. Blunt methods of division are to be shunned, as torn tissues are not so viable as cut ones and are apt to succumb very easily to septic influences that may proceed from an ulcerating or sloughing œsophagus. The incision should be just in front of and parallel with the anterior border of the left sterno-mastoid muscle, beginning a little below the level of the cricoid cartilage and extending to the sternal insertion of the muscle. The omo-hyoid is drawn aside, and the lateral margin of the thyroid gland is exposed to serve as a guide. The large vessels should remain undisturbed within their common sheath, and are to be drawn backward and aside, together with the sterno-mastoid. Dissection should proceed between two mouse-tooth forceps.

Thus vessels crossing the tract of the incision can be recognized and secured before being cut. Should the sternal portion of the sterno-mastoid be in the way, it may be cut also. The recurrent nerve must not be injured. The œsophagus can be recognized by the longitudinal direction of its fibers, or, if this is difficult, by protrusion practiced with a metallic catheter or urethral sound from within. It is incised between two small, sharp retractors, and fillets of silk are passed through the edges of the cut, by which manipulations within the viscus are made much easier. In the absence of septic complications—and this may be fairly expected in cases receiving early attention—the edges of the œsophageal wound should be stitched at once with fine silk. The outer wound is to be packed loosely with iodoform gauze. A few silk-worm-gut stitches may be inserted into the cutaneous edges of the wound, which, however, is to be closed only after the removal of the packing. In these cases alim-entation by the mouth can be commenced at once with liquid substances, and the patient should swallow very small quantities and while lying on the right side. Minute leakage will often occur, but will not interfere with the rapid healing of the wound. In those cases where ulceration or sloughing has occurred, suture is often impracticable and rarely safe. The open method by packing is in order, and large defects may necessitate the use of the stomach-tube, which can be inserted through the wound or by the mouth or nares.

The following cases may serve as illustration of these remarks:

CASE I.—Margaret Kurtz, aged nine years, swallowed a bi-convex tin whistle on March 22, 1889. The family attendant, Dr. Katzenmayer, had made a large number of unsuccessful attempts to dislodge and remove the body, which could be easily reached by the mouth. On March 29th the writer took charge of the patient at the German Hospital. The foreign body could be easily grasped by suitable forceps, but would yield neither to traction nor pressure. It was firmly held in the region of the thoracic aperture. Œsophagotomy was done at once under chloroform. When the body was grasped through the wound with a short, stout forceps, considerable manipulation was needed to change its position and to extract it. The œsophagus was sutured; the outer wound packed. Alim-entation with milk began the next morning. No leakage. Thirteen days after the operation the patient was discharged cured, without having had any febrile disturbance.

CASE II.—Samuel Brisander, two years old, swallowed a penny on March 28, 1889. Since then only liquids could be swallowed. The child complained of pain in the abdomen. Eleven days after the accident the patient was admitted into Mount Sinai Hospital. On April 9th—that is, on the twelfth day—the writer examined the child in anæsthesia. There was no fever. A metallic body could be identified by click seven inches and a half from the lower incisors, but all efforts at its dislodgment or extraction were futile on account of the smallness of the space. Fearing that an ulceration was present, no attempt was made to push the body into the stomach. Œsophagotomy was at once performed in the usual manner. The penny, which was very firmly grasped by the walls of the œsophagus, was dislodged and extracted, not without difficulty. The œsophagus was sutured, the outer wound packed, and nutrition commenced at once. Slight leakage was noted on the third day after the removal of the first packing, but in three days more it ceased.

No febrile or local reaction was observed. On April 14th the child became sick with the measles, and, though the wound had healed kindly within a fortnight, the patient's discharge was delayed till May 11th by this complication.

It can be fairly assumed that most œsophagotomies performed early and with the proper observance of technique would yield as favorable results as the ones here recorded. The dangers caused by the impacted body, especially if it is jagged and prone to putrescence, are infinitely greater.

Though no œsophagotomy was performed in the last case, to be reported presently, yet so many points of interest and importance are illustrated by it that it deserves to be put on record.

CASE III.—Fanny Stiner, forty-three years old, a poorly nourished, anxious-looking woman, had swallowed a fish-bone on April 1, 1889. Since then she had felt considerable pain in the left side of her throat and been unable to swallow anything but liquids. On April 9th a painful swelling was observed corresponding to the left lobe of the thyroid gland, which extended well backward under the sterno-mastoid muscle. Though the body temperature was normal, the woman showed a state of marked depression, with a rapid and small pulse, and her respiration was markedly stridulous and embarrassed. Search was made in the œsophagus for the foreign body ineffectually. As subsequent events showed, it could not be found there because it was not there. Chloroform being administered, the posterior edge of the thyroid gland was exposed as in œsophagotomy. It was found that the left lobe of the thyroid gland was tumescent and very hard. With an aspirator extremely fetid pus was withdrawn from the gland, whereupon this was freely incised and about two ounces of ichorous pus were evacuated from a cavity, the inner wall of which was formed in part by the left lateral aspect of the trachea and œsophagus. From the bottom of this cavity was extracted a fish-bone which apparently had found its way there from the œsophagus. The cavity was packed and the wound treated by the open method. Recovery was slow, though the reaction was mild, and the swallowing rapidly improving. On May 10th the patient was discharged cured.

The great importance of an early incision of phlegmonous foci caused by perforating foreign bodies originally impacted in the œsophagus need not be insisted on at this date. Waiting for the appearance of fluctuation is too risky on account of the destructive character of the inflammation, and a methodical dissection guided by anatomical knowledge is the only proper thing.

## THE PROGRESS OF CYSTOSCOPY IN THE LAST THREE YEARS.

By WILLY MEYER, M. D.,

ATTENDING SURGEON TO  
THE GERMAN AND NEW YORK SKIN AND CANCER HOSPITALS.

(Continued from page 119.)

### II. CYSTOSCOPY WITH REFERENCE TO DISEASES OF THE BLADDER.

To give an accurate account of everything of interest that has so far been seen in the bladder and published is a difficult task and one of no intrinsic value. The literature

on cystoscopy, which has appeared mostly within the last three years, is already very large. Nitze's so often mentioned fundamental and instructive *Text-book on Cystoscopy*, Hurry Fenwick's valuable, lucid, and extremely interesting work, *The Electric Illumination of the Bladder and Urethra*, as well as also many other articles bearing on the same subject, written by different men, fully cover the ground. The appearance of these writings within the very last years renders an attempt in this direction at my hands a work of supererogation. The manifold brilliant results as enumerated in this part of medical literature demonstrate how often and sometimes easily an exact diagnosis of a previously obscure urinary disease can be and has been established with electric illumination of the bladder. These results fully sustain Nitze's original statements and predictions in every particular—namely, that the present electric illumination of the bladder gives us the means of establishing a strict differential diagnosis between the various forms of catarrh of the bladder—acute,\* chronic, hæmorrhagic, diphtheritic; that it is easy to see with it ulcerations, to demonstrate diverticula, to find and localize foreign bodies; that it seems almost unnecessary to mention how plainly we can now see stones, make out their number, size, shape, and mobility, and percuss them with the beak of the instrument; how encysted stones, too, will not escape the examining eye; that especially the diagnosis of tumors of the bladder is now easy and can be made early.

It is obvious how strongly this exact diagnosis at once reflects upon prognosis,† indication, and treatment. Not infrequently an unnecessary operation can thus be avoided. Certainly it has been sufficiently established that if any doubt exists of the diagnosis in a case of vesical disease and the three cardinal conditions which enable a cystoscopic examination to be made ‡ are fulfilled, it is the duty of the attending physician to submit his patient as early as possible to this ocular inspection. This on the same ground as he would look with the help of a mirror at the interior of the larynx, eye, nose, or ear in their respective disorders.

A few cases of my own, each representing a different chapter of vesical disease, selected from a large number of interesting cystoscopies, perhaps deserve to be briefly reported in this place. In every one of them (the one sub *a* alone excepted) the cystoscopic diagnosis was verified in the subsequent operative interference. I shall omit cases illustrating the various forms of catarrh (localized and general) and the hypertrophy of the lateral lobes of the prostate, although they were frequently met with.

\* In cases of acute catarrh the use of the cystoscope is, of course just as much to be prohibited as that of a catheter or sound.

† Fenwick believes he has seen and found a peculiar condition of the vesical mucous membrane which he calls "pre-cancerous." *The Elect. Illum.*, etc., p. 153; also *Brit. Med. Journal*, September 22, and October 13, 1888.

‡ 1. The caliber and shape of the urethra must permit of passing the cystoscope into the bladder. 2. There must be sufficient capacity of the bladder (average = 5 ounces). 3. The fluid in the bladder must be transparent, at least during the time of examination (cf. irrigating cystoscope). See author on Cystoscopy and the New Cystoscopy of Nitze and Leiter, with a Demonstration of the Same, *N. Y. Med. Journal*, April 21, 1888, p. 429.

*a. Tuberculous Ulceration.*—Mr. H. C. E., aged forty-five years, married, came to me for examination through the courtesy of Dr. L. G. N. Deanslow, of St. Paul, in April, 1890.\* Twelve years ago first pain in glans penis, which in the following ten years often gave rise to trouble. Two years and a half ago first appearance of blood and mucus in urine, with increased pains in glans. November, 1889, a large, painful swelling in the right lumbar region, which had formed under considerable rise of temperature, nearly disappeared after the passage of a large quantity of pus with the urine. One month later last hæmaturia at the end of micturition. Present condition: Greatly reduced man; pains in glans penis if bladder is full. Urinates every two hours day and night. No tenesmus, no stoppage. Right kidney palpable, slightly painful on pressure. Urine only slightly turbid; contains a large amount of tubercle bacilli in every microscopical specimen. Cystoscopy (Nitze's cystoscope, No. 1): Immediately above the swollen mouth of the right ureter and its elevation of mucous membrane an ulcerated spot of about the size of two silver dollars appears. Purplish-red, broad elevations (evidently the inflamed fibers of the detrusor muscle) cross each other in different directions. Small particles of snowy, shining mucus, adherent to their surface, float in the fluid. The depressions between these elevations are of a lighter hue, also covered with mucous flakes. In between them numerous very small and larger sessile growths of grayish coloring are plainly visible, a few about as large as a pin's head, undoubtedly *miliary tubercles*. On one spot a small rhomboid-shaped, dark-red (hæmorrhagic) spot can be seen. The entire other inner surface of the bladder is perfectly normal, of grayish-white color, rather anæmic, corresponding with the condition of the patient† As I was informed by Dr. D. some time ago, the right kidney was lately removed, with great benefit in regard to the patient's general condition. It had been converted into a large pus-sac.

*b. Diverticulum.*—Mr. J. P., aged sixty-four, had come under my care in the summer of 1888 on account of an intense catarrh of the bladder, due to hypertrophy of the prostate of long standing. Urine of fætid smell, voided every few minutes. Cystoscopy (Leiter, No. 1). Mucous membrane of dark-grayish appearance, nearly black. Shreds of mucus and necrotic tissue adherent to the wall, floating in the injected water. No diagnosis made. Subsequent examination of urine showed a far advanced diabetes which so far had not been diagnosticated. Strict antidiabetic regimen brought comparatively quick relief. Cystoscopic (probable) diagnosis then advanced: diabetic superficial gangrene of the mucous membrane of the bladder.‡ About one year later cystoscopy (Nitze, No. 1) was again performed: All symptoms of chronic catarrh, *vesicæ à colonnes*; a little out-

\* Cf. the author's review of Nitze's *Text-book on Cystoscopy*, *Annals of Surgery*, June, 1890.

† It has to be stated that the cystoscopic picture of a tuberculous infiltration has not yet been established. A failure in making the diagnosis of tuberculous non-ulcerative cystitis with the cystoscope before the suprapubic incision is resorted to for clearing up the obscure trouble is no reproach to this mode of examination. If tubercle bacilli have been found in the urine before cystoscopy is tried—and they will be by far easier found, even in a relatively clear urine and if present in a very minute quantity, by the centrifugal method of Stenbeck, modified by v. Frisch (*Zur Diagnose der tuberkulösen Erkrankungen der Urogenitalsystems*, *Internat. klin. Rundschau*, 1891, Nos. 28–30)—a localized hyperæmic spot of the vesical mucous membrane seen through the cystoscope has to be diagnosticated as being most probably one of tuberculous character (tuberculous infiltration). It is to be hoped that such cases, if made out in this manner, will henceforth be published in detail.

‡ Author, *N. Y. Med. Journal*, February 23, 1889, p. 20.

ward of the mouth of the left ureter a large, dark spot of about a five-cent piece is seen. Its lining mucous membrane is wrinkled. The light of the cystoscope is then turned off and the tip, posted right in front of this spot, gently pushed forward. It evidently enters a cavity but touches no concrement. Diagnosis: diverticulum. Operative interference for the hypertrophy of the prostate is not proposed, as patient is satisfied with the use of the catheter. Strict antidiabetic regimen. Two years later patient has to catheterize himself every fifteen to twenty minutes; constant pain, fever, seven per cent. sugar. Epicystotomy becomes imperative and shows a large diverticulum at the diagnosticated spot filled with phosphatic *débris*.

*c. Foreign Bodies.*—B. v. P., aged forty-one, was admitted to the German Hospital on May 22, 1888.\* He had always been a healthy man up to three years ago, when left renal colic with hæmaturia had first appeared. The latter had been intermittent since then. Frequently the first drops were mixed with blood during micturition; then the urine was clear. Now and then he passed pure blood. According to the advice of one of the gentlemen whom he had consulted abroad, he had for a long time had his bladder flushed daily with a mild solution of permanganate of potassium. Two months before entering the hospital a severe catarrh of the bladder had set in. With great strain small particles of a semi-solid substance had now and then been voided through the urethra. Frequent stoppage of flow of urine; great pains; morphine habit. On examination, the searcher did not strike stone. Urine, muddy and of alkaline reaction, contains three per cent. albumin. Under the microscope: red blood-corpuscles, pus and mucus, no casts. A tumor of about two fists' size with a smooth surface, evidently belonging to the left kidney (tumor or pyonephrotic stone-kidney?), can be palpated in the left hypochondrium of the anæsthetized patient. Cystoscopy under chloroform (Nitze, No. 1): As soon as the instrument had entered the bladder and the light had been turned on, I saw a few (six to eight) curiously shaped more or less flat curved bodies of black color, covered with whitish deposits of phosphates. Stirred up by the outflowing streams of urine from the ureters, they constantly tumbled over each other and were thrown against the beak. No click, however, was noticed; their consistence was soft. Besides these bodies there was no stone, no tumor, only evidence of catarrh.

To establish a diagnosis with reference to the nature of these bodies from this cystoscopic picture was entirely impossible. None of those present had ever seen anything like them. The most probable supposition seemed to be that of coagulated blood, which had descended from the left kidney. Still the semi-solid condition and peculiar shape of the bodies remained unexplained. Nevertheless the result of cystoscopy was highly satisfactory. The cause of all the vesical trouble had been found. No searcher, no bimanual palpation could ever have accomplished anything like it. When the bladder was incised—above the pubes—about eight bodies of various size could be easily extracted. They were of a semi-solid, black substance, flexible, and covered with phosphatic deposits, just as they were made out through the cystoscope. Chemical analysis showed that they consisted of sixty per cent. fibrin and forty per cent. permanganate of potassium.

*d. Stones.*—CASE I.—Mr. D., fifty three years old, † merchant, for several years troubled with chronic gastritis, was seized with pain in the glans penis and in his left lumbar region in the fall of 1886. After three days the pain left him and did not return until a year later, September, 1887, when he developed symptoms of stone in the bladder. Neither hæmaturia nor stoppage

\* *N. Y. Med. Journal*, 1889, p. 198.

† *Ibid.*, p. 199.

of the flow of urine had ever been present. A thorough examination with the searcher repeatedly performed at that time by a very able surgeon failed to detect stone, and the patient was therefore put on suitable internal medication. But as his condition got steadily worse, his family physician courteously sent him to me for cystoscopy June 11, 1888. The patient's bladder being extremely irritable, and examination with the searcher having been accompanied and followed before by great agony, I yielded to the patient's urgent request and immediately introduced the cystoscope (Leiter, No. 1). Having turned the instrument 180°, thus directing the prism toward the fundus of the bladder, I saw at the first glance in brightest illumination an oval-shaped, brownish body covered with white spots (evidently phosphatic deposits) of the size of an almond, lying in the pouch behind the enlarged prostate. It threw a distinct shadow upon the opposite wall of the bladder. I then turned off the light and touched the body with the tip of the instrument. I got an unmistakable click. The bladder otherwise presented symptoms of catarrh. The ureteral openings emitted a clear and transparent fluid. No further special attention was paid to the character of the jets of urine coming from the ureters at that time, as no symptoms indicated a diseased kidney.

Suprapubic lithotomy was performed and the stone easily removed. It presented the characteristics as seen with the cystoscope.

CASE II.—Mr. X., always healthy, is suddenly unable to urinate. A doctor tries to introduce a soft-rubber catheter, but does not succeed. When I saw the patient in consultation my perforated sound struck a hard substance just at the neck of the bladder, which slipped back into the viscus. Nearly two quarts of urine were voided. The patient then was all right. Three days later retention for a second time set in, and was again relieved by catheterization. I was convinced that there was a small stone in the bladder, but was unsuccessful in striking it with the searcher. The cystoscope (Nitze, No. 1), of course, gave at once evidence of a small, uneven concretion, about half an inch long, not unlike a small dried bean. I proposed to try and aspirate it with Otis's evacuator. Meanwhile the stone again blocked the urethral canal, but, with the help of a sudden forcible strain, was expelled, to the greatest delight of the patient. Its characteristics were found as stated in my letter to the colleague.

*e. Hypertrophy of the Median Lobe of the Prostate.*—X., aged seventy, relies entirely upon catheter, which has frequently to be passed. Passage attended by difficulty and pain. Two strictures—one in the anterior, the other in the posterior portion of the urethra—had been divulged about a year before, and then the bladder carefully washed for some time. Urine was clear—no blood, no pus, no albumin, no casts; great local distress. Cystoscopy (Nitze, No. 1, long): In introducing the instrument its handle had to be pressed far down before the beak enters the bladder. A slightly hypertrophied third lobe, of about half to three quarters the size of the third phalanx of the middle finger, is easily diagnosed; the bladder presents a *vesicæ à colonnes* in a most beautiful manner. Soon afterward suprapubic cystotomy was performed by another surgeon. The third lobe was found as diagnosed, and pinched off with the rongeur.

*f. Tumors.*—Out of a greater number of these cases I cite the following two, which may serve as paradigms:

CASE I.—Mr. X., aged fifty-three years,\* was seen by me in consultation on March 20, 1890. For six months he had nearly continuously passed bloody urine without submitting to a close

examination. He had suffered from frequent forcible micturition and intermittent pain in the glans; otherwise he had felt comfortably. Repeated careful chemical and microscopical examination only showed red blood corpuscles and mucons cells, never a particle of a new growth. Bimanual palpation was very difficult, and also promised no result on account of the patient's great corpulence and marked hypertrophy of the prostate. I therefore immediately resorted to cystoscopy. As a hypodermic of morphine, with local cocaine anæsthesia, did not quiet the irritable bladder, the patient was narcotized. Now I saw in brightest illumination a round sessile growth with an uneven surface, not unlike a large round strawberry, on the left wall of the bladder, about an inch above the mouth of the left ureter. I very plainly observed that blood was oozing out of its surface. The other portion of the interior of the bladder appeared to be healthy; there were symptoms of a slight catarrh.

Diagnosis.—Cancerous sessile tumor of the bladder.

Suprapubic cystotomy, March 25, 1890 (performed as usual in Trendelenburg's posture). Growth, on the spot localized before, presented all the characteristics as formerly diagnosed with the cystoscope. It was, with the adjacent parts of the wall of the bladder, cut out with the knife by an ellipsoid incision. The base was then carefully burned with Paquelin's thermo-cautery. Uninterrupted recovery. No recurrence till date.

CASE II.—Mr. J. B., aged forty-eight years, had been in perfect health up to May, 1889. At that time he had a sudden and causeless attack of hæmaturia, which ceased as suddenly after forty-eight hours, but only to return after a few weeks. The bleeding then became intermittent, appearing first about every one, two, or four months, later in as many weeks. Pain in glans and frequency of micturition also were experienced. January, 1890, retention caused by clots. The catheter brought relief, but started catarrh. The patient had consulted different doctors, but only irrigation had been advised. One colleague proposed suprapubic incision without having strictly diagnosed the case. Cystoscopy on May 12, 1890 (Nitze, No. 1); five ounces thrown in. On turning the beak to the left side and slightly directing the prism toward the floor, a large, cock's-comb-like, pinkish-red tumor is at once detected. Deep, irregular furrows divide the surface into larger and smaller, uneven, and lobulated areas, which bleed when touched with the beak of the instrument. The growth is planted on a thick and succulent base, a little outside of the left ureteral orifice, and embraces an area of at least a silver dollar. Illuminated by the electric light—the peaks and plateaus in brightest sunshine, the many irregular wounded valleys, out of which a few trickling streams of blood slowly find their way, in dark shade—the appearance of the whole succulent, erect, and pulsating growth was picturesque in the extreme. Nearer to the fundus and the median line a second smaller tumor is seen about as large as a cherry. The interposed portion, as well as the whole of the interior of the bladder, appears healthy.

Diagnosis.—Cancer of the bladder, still extirpable.

When the bladder had been opened above the pubes, the condition corresponded exactly to my cystoscopic diagnosis, which I had before explained to the gentlemen who kindly assisted me during the operation. The large tumor was shelled out in healthy tissue with Paquelin's thermo-cautery knife. Two large spurting arteries which entered the base of the growth and fed it were ligated with medium-sized silk, as catgut seemed unreliable and the bladder was to be drained. They could be easily tied, as they had been torn about an inch above the inner bladder surface. The smaller cancer was cut out with the knife and its insertion carefully burned. Tamponade with iodoform gauze; drainage for twelve days. Quick recovery. Seven

\* Cf. *Annals of Surgery*, l. c.

months later I had to extract a longitudinal small stone from the patient's urethra. Nucleus: a silk ligature! Seven weeks later the patient again called on me on account of great distress and hæmaturia. On introducing the cystoscope I saw in the fundus a stone, of at least almond-size, covered with mucus and phosphates, and in the upper inner angle of the flat, whitish, shining scar (the result of the former operation) a small, stalked recurrent growth, of cauliflower shape, overhanging the mouth of the ureter and swaying at every eddying rush of the ureteral streams.

In view of this complication, I proposed and performed suprapubic cystotomy for a second time. The stone was easily removed (its nucleus was the other silk ligature), and the bleeding spot, where the recurring tumor had been inserted, thoroughly burned. To-day patient is doing well. (This case will soon be published *in extenso*.)

Before closing this section I ought to say that the cystoscopic diagnosis in bladder diseases is not at all always so easily made. First of all, it must be borne in mind that this ocular inspection can not be applied in every case, and that, if it can be resorted to, it requires *in praxi* a great deal of patience and, to avoid mistakes, also experience. The three cardinal conditions which alone guarantee a successful examination should be carefully investigated *before* the instrument is introduced. If one of them can not be fulfilled, a failure may be expected. Although I am well aware that we may be able to make a correct diagnosis, after some experience at least, with only from three to four ounces of water in the bladder, still I have made it a point—and I would especially give this advice to the beginner—always to try and have five ounces thrown in. We know, from Nitze's investigations, that this amount just expands all the folds and grooves of the intravesical surface. The only exception from this rule I make is in cases of supposed tumor of the bladder with obstinate hæmaturia, but without a marked vesical catarrh. Here the cystoscope is introduced as soon as the bleeding has ceased, and probably a sufficient amount of urine is in the bladder. Washing will frequently start the hæmorrhage again. (If we wish to increase the capacity of the bladder, we must inject the fluid forcibly with the syringe, and not use the irrigator; and even then we may sometimes be unsuccessful.) Only in this way, by training our eyes to inspect the surface of the properly and more or less always equally expanded viscus, can we hope to learn by and by how to avoid the many pitfalls which await the cystoscopist. If the surface of the prostate begins to bleed at the slightest touch of a solid instrument, I at once try to examine with the irrigating cystoscope and have the nurse throw water in while the beak passes the posterior urethra and neck of the bladder.

We also have to pay attention to the magnifying power of the Nitze telescope as well as to the fact that the nearer the prism the larger the object. If after a careful examination and deliberation there is still doubt with reference to explaining and identifying the image observed, a second cystoscopy should be insisted upon.

Lastly, the cystoscopist should accustom himself, especially in cases which he sees in consultation, first to obtain a thorough history, then to make a general examination, especially with reference to tuberculosis, to carefully analyze

the urine, to palpate the lumbar region of each side, the testicles, and the prostate, and test the caliber of the urethra. The operator should always start with the case as if he did not yet possess the cystoscope to enable him to view the interior of the bladder. He should push his means of diagnosis as far as possible by rational signs and examination of the urine. But the first instrument he then takes in hand should be not the sound, but the cystoscope. Only when a stone in the bladder is strongly suspected should the sound be used first.

Here are a few examples, for the beginner as well as for him who uses the cystoscope without a previous general examination, as just explained, and also possibly fails to read the literature beforehand and thus benefit by the experience of others:

He will easily take the taggy shreds of necrotic tissue, hanging at the edge of a tuberculous ulcer and floating in the fluid, for a polypus, without at all noting the ulcer, especially if the prism is brought close to it (the experienced and careful examiner has probably found before tuberculosis of the testicles, or an enlarged kidney, or tubercle bacilli in the urine, or such a detritus under the microscope which will lead him to suspect the existence of an ulcer and thus make him look out for it); he will take the prolapse of the ureter for a sessile growth (but if the prism is carried near by, this growth is entirely transparent, and on careful inspection it will be seen that out of one spot of its perfectly round and smooth surface a whirl of urine will suddenly be expelled).

He will take an incrustated growth for a stone (a touch with the beak will quickly dispel any doubt); a deposit of coagulated blood around one of the ureteral cones will perhaps puzzle him (the experienced will take it as a hint at hæmaturia of renal origin, most probably on the same side), as will also the picture of the enlarged median lobe of the prostate.

Success will not be with him if the just injected clear fluid turns murky at once after a long-continued irrigation, or is found to be so as soon as the cystoscope has entered the bladder. (The experienced man at once suspects kidney trouble, will exchange the ordinary for the irrigating cystoscope, and watch, after a quick glance at the interior of the bladder, the ureteral orifices. Most probably pains or the already palpated swelling in one lumbar region will guide him on which side to look first.)

Of course an infiltrated spot in the wall of a bladder which can not be properly distended, or greatly hypertrophied and easily bleeding rugæ in a case of localized chronic catarrh, will also easily mislead the well-trained eye and induce one to diagnosticate a tumor where the suprapubic incision will merely show infiltration. Also many other mistakes may occur. But they will become rarer with increasing experience; and if, nevertheless, they still occur, the physician may console himself with the reflection that mistakes occur just as often and as easily in the other and older branches of surgical diagnosis.

(To be concluded.)

## DISEASES OF THE URINARY APPARATUS.

By JOHN W. S. GOULEY, M.D.,  
SURGEON TO BELLEVUE HOSPITAL.

(Continued from page 128.)

## PART I.—PHLEGMATIC AFFECTIONS.

## SECTION II.—SPECIAL CONSIDERATIONS.

## XI.

CONSEQUENCES OF ACUTE URETHRITIS CONTINUED; GONOCYSTITIS, TRACHELOCYSTITIS, PYELITIS, SEPTICÆMIA, PYOSAPRÆMIA, AND RHEUMATISM.

THE investigations upon which is based the part of this conference relating to the seminal vesicles began in 1879, but were interrupted by other occupations, and were not resumed until the year 1889. The majority of the dissections exhibited were made during 1889, 1890, and 1891. The specimens for dissection were kindly contributed by a number of medical friends interested in pathology.

GONOCYSTITIS—phlegmasia of the seminal vesicles—is of much more frequent occurrence than is generally supposed. It exists more commonly as a chronic affection, often associated with trachelocystitis and prostatitis, for both of which it is very frequently mistaken.

Most practicing physicians have had their share of cases of chronic urethral discharge accompanied with phenomena variously styled “genital hypochondriasis, sexual neurasthenia, diurnal spermatorrhœa, sterility, impotency,” etc. The majority of these are cases of chronic gonocystitis. Their cure is very difficult, slow, uncertain, and sometimes impossible. It is not easy to persuade the patients that the disease is local and that there is no great danger of implication of other organs. Dwelling much upon and magnifying their infirmity, their moral condition is soon not a little impaired. They are often unheeding of good advice, and, after having “gone the rounds” of the regular profession, fall into the meshes of greedy charlatans, while some of them end their days in asylums for the insane.

In its acute type gonocystitis frequently occurs as one of the consequences of urethritis with orchitis. It is then very often overlooked, because the phenomena of the orchitis occupy so much of the attention of the patient that the subjective symptoms referable to the region of these vesicles are masked by those of the orchitis. Therefore, in order to ascertain the existence or non-existence of acute gonocystitis, it is necessary to put well-directed questions to patients suffering from urethritis and consecutive orchitis accompanied by abnormal sensations in the intrapelvic organs. Prior to the further study of this phlegmasia it may be advantageous to rehearse the main points of the anatomy of the parts involved.

THE SEMINAL VESICLES, PHYSIOLOGICALLY CONSIDERED, are diverticula of the spermatic canals serving as reservoirs of the semen in man and most of the mammalia, notwithstanding the opinion of John Hunter to the contrary. The assertion that the seminal vesicles are physiologically diverticula of the spermatic canals is based upon the following

facts: The dilated part of the spermatic canals corresponding in longitudinal extent to the seminal vesicles is identical in structure with the seminal vesicles; the same kind of fibrous, muscular, and mucous coats exist in both; the mucous coat is rugous and reticulated and lined with the same kind of epithelium in both; the same kind of mucus is secreted by the same kind of mucous glands in both; certain expansions and diverticula are found in both; concretions abound in both; and both are tubular in character. The anatomical differences are: The tube of the vesicles is more convoluted than the spermatic canals; the walls of the vesicles are thinner than those of the spermatic canals; the caliber of the tube of the seminal vesicles is greater than that of the spermatic canals; and the seminal vesicles have twice as many pouches as the spermatic canals. Each vesicle is therefore only an extension of the spermatic canal. In some animals—the dog kind, for instance—there are no seminal vesicles, the slightly expanded extremity of the spermatic canals doing all that is necessary toward diluting the semen before it reaches the prostatic region of the urethra. The seminal vesicles of a horse dissected in 1890 do not consist, as in man, of a single convoluted tube with diverticula, but each vesicle is an oblong sac capable of containing at least two ounces of fluid. The mucous membrane is rugous at the posterior extremity of the sac; the remainder is smooth.

One vesicle lies on the right and the other on the left of the median line, each with a spermatic canal on its inner border, widely separated posteriorly and converging anteriorly to the base of the prostate, which is traversed by their excretory ducts, and to which their anterior extremities are closely united; the vesicles and accompanying spermatic canals forming two sides of an isosceles triangle, and being attached to the lower fundus of the bladder, with its rest upon the rectum. The close relations of the vesicles to the prostate, bladder, rectum, and peritonæum explain how these parts are liable to be reciprocally involved in disease. When, in health, the bladder is empty, the space between the posterior extremities of the seminal vesicles is two inches and three quarters in extent, but while this part of the bladder is thus increased in width it loses in antero-posterior extent, for the peritonæum descends to within half an inch of the base of the prostate; and in some cases even overlaps the base of the prostate. When the bladder fills up with urine the peritonæum ascends with it and this antero-posterior space is more than doubled, while the transverse—*i. e.*, the space between the posterior extremities of the seminal vesicles—loses three quarters of an inch.

Each vesicle has a proper fibrous tunic, and the two have besides a common fibrous envelope containing a considerable amount of smooth muscular tissue, which connects them superiorly with the bladder, while they are attached to the rectum by loose connective tissue. The vesicles derive their nutrition from branches of the inferior vesical and middle hemorrhoidal arteries. Their veins are large, and form a plexus which pours its blood into the efferent veins of Santorini's plexus, and which renders excision of the vesicles so bloody and dangerous an operation as it has proved to be. The lymphatic vessels are abundant and end

in two or three trunks on each side, which enter certain glands on the sides of the pelvic excavation. The nerves are derived from the hypogastric plexus.

The seminal vesicles are conical in general outline, their bases are rounded and in close proximity to the recto-vesical *cul-de-sac* of the peritonæum, and their apices are buried in the base of the prostate. They are slightly flattened superiorly and convex inferiorly, and when distended show very distinctly their convolutions, which are bound together by connective tissue. They measure five centimetres (about two inches) in length and when unraveled twelve centimetres (about four inches and three quarters) in extreme length, exclusive of their eight or ten diverticula. The caliber of the tube of the vesicles averages six millimetres. This tube, like the spermatic canal, is made up of three layers—an external fibrous, very thin layer; a middle, consisting of smooth muscular tissue, the thickest of the three; and an internal, mucous layer. The mucous layer is rugous, alveolar, lined with a cubical epithelium, and contains caecal glands—such as are found in the terminal part of the spermatic canals. These glands are parallel to each other, are ordinarily single, but here and there are double, triple, quadruple, or even quintuple, converging to a common duct which opens between the rugæ, the clear mucoid substance they secrete serving to dilute the semen.

Each vesicle has its excretory duct, which, uniting with the spermatic canal, forms the common ejaculatory duct, which is about sixteen millimetres in length, slightly conical in form, and opening by a slit on each side of the *veru montanum* on the floor of the prostatic region of the urethra. The caliber of the common ejaculatory duct is about two millimetres at its upper extremity, decreasing to about one millimetre at its terminal extremity in the urethra, and is extensible to a considerable degree. Its parietes are very thin as compared with those of the seminal vesicle, and its mucous membrane is smooth.

The seminal vesicles, as is seen from their peculiar construction, serve the double purpose of reservoirs of the semen and of accessory glands to the genital apparatus, their alveoli, diverticula, and convolutions preventing them from completely emptying themselves during ejaculation. In them the semen is detained long enough not only to be diluted by their mucoid secretion, but for the spermatozooids to attain full maturity. In the semen of men given to excessive sexual intercourse, immature spermatozooids have been found still inclosed in their parent cells. This seems to sustain the view that the spermatozooids do not reach perfection until they have lingered for a time in the lower part of the spermatic canals and in the seminal vesicles.

Besides secreting the mucoid substance already referred to, the seminal vesicles contain certain very small calcareous concretions, few in number and not constantly found except in disease. Civiale mentions Carmann, Riedlin, Stalpart Vander Wiel, Hartmann, Meckel, Hemman, and Baillie as having cited examples of calculous concretions formed in the seminal vesicles, and likewise names Mitchell as having found two hundred small calculi, of earthy appearance, in the right seminal vesicle of a phthisical subject. Rokitsky also speaks of the presence of calculous concretions in the semi-

nal vesicles. In addition to these calculous particles, there is a great abundance of other concretions, irregular in form and size, nearly colorless in health, amber-colored in disease, very friable, and resembling inspissated mucus. These last-named concretions, whose use is unknown, were carefully studied by Ch. Robin, who called them *sympexia*, which means concretions, and who thought them analogous to the concretions found in the thyroid body, the spleen, the glands of the uterus, the lymphatic glands, and the prostate. These *sympexia* are found in great quantities also in the expanded extremities of the spermatic canals. Microscopic in dimensions, they are lodged in the alveoli of the mucous membrane, increase in size from phlegmasia of this membrane, and become sources of further irritation, and even obstruct the excretory duct, as observed in some of the specimens exhibited. In these specimens they vary from one to four millimetres in mean diameter, and among the specimens illustrating chronic gonocystitis many are oblong, like grains of rice, three by eight millimetres in dimensions. The large *sympexia* sometimes consist of aggregations of small concretions cemented by pus and imprisoning spermatozooids, blood, and epithelial cells. They fly to pieces on slight pressure.

The normal seminal vesicles of a man, aged thirty-nine years, who died of pneumonia, were carefully dissected and the contents of the left vesicle examined microscopically, with the following results: The fluid was viscid, of a brownish color, and consisted of mucus, with innumerable spermatozooids, spermatic cells, leucocytes, a few cubical epithelial cells, and great numbers of *sympexia* of a yellowish color, globular in form, some of them about half the diameter of red blood-corpuscles, others of nearly the size of red corpuscles. Here and there these *sympexia* were aggregated in masses from the one five-hundredth to the one three-hundredth of an inch in size.

The viscid, brownish contents of the seminal vesicles of a man, seventy-three years of age, who died of a head injury, examined microscopically, twenty-four hours after death, consisted of epithelial cells of different form; some were polygonal, some cubical, some oval; a few spermatic cells, many *sympexia* of amber-color, varying in size from one third the diameter of red blood-cells to the size of leucocytes; some of them were round, the majority polyhedral and irregular, and the smallest were often aggregated in masses of four, six, eight, or ten. No spermatozooids were discerned. Other observations gave similar results. The cubical character of the epithelium and the existence of mucous glands were verified in the vesicles as well as in the spermatic canals.

GONOCYSTITIS does not appear to have attracted much attention until Lallemand published his observations of this affection in connection with "spermatorrhœa," which is often one of its phenomena, while some form of urethritis is almost invariably its exciting cause. Civiale, Vidal, Gosselin, Verneuil, Fournier, Rapin, and other authors, French, German, English, and American, have, to a greater or less extent, discussed the question of phlegmasia of the seminal vesicles in special essays, general surgical treatises,

inaugural theses, or journal articles. Among the essays that have appeared in the last few years upon this topic is a paper with the title of Seminal Vesiculitis, by Mr. Jordan Lloyd, of Birmingham, in the *British Medical Journal*, April 20, 1889. Each of these writers has contributed his share toward the elucidation of the subject, but much remains to be done by other laborers.

Gonocystitis seems to occur with greatest frequency among men who habitually commit venereal excesses, and among those addicted to inasturbation, either rendering the seminal vesicles more or less vulnerable. This vulnerability generally consists in abnormal expansion of the ejaculatory ducts, or in persistent erethism of their mucous membrane and that of the seminal vesicles. Acute phlegmasia of the urethra in such subjects is thus propagated through the ejaculatory duct to the seminal vesicle and spermatic canal on one or both sides, generally accompanying orchitis, but sometimes without the association of orchitis, just as orchitis often occurs without involvement of the vesicle. It arises most commonly as a consequence of chronic urethritis, but violent catheterism is not infrequently its exciting cause, particularly when a very small instrument enters or tears the ejaculatory duct.

In the acute types of gonocystitis the mucous membrane of the ejaculatory duct may be swollen to the extent of occluding its lumen, or a large sympexion may be dislodged from the vesicle, forced into, and plug the ejaculatory duct, so that in either case pus may accumulate and greatly distend the vesicle whose attenuated, or perhaps ulcerated, walls are finally perforated, possibly at several points, allowing this pus to infiltrate the ambient connective tissue and to form a vast abscess pointing in the direction of the ischio-rectal fossa, of the bladder, of the rectum, or even of the peritonæum. This process belongs generally to superacute or to acute phlegmasia. In the case of subacute phlegmasia there is a minor degree of swelling; resolution being slow or failing, there follows chronic gonocystitis, interstitial as well as parenchymatous.

In the chronic type there is sometimes ectasia of the vesicles, which contain large sympexia, as shown in several of the thirty-four carefully dissected specimens exhibited, or the vesicle shrivels sometimes in an extraordinary degree, as seen in three of the specimens, and becomes useless. One specimen illustrates three interesting points: occlusion of the right spermatic canal, shriveling of its accompanying seminal vesicle, and apparently compensatory enlargement of the left vesicle and spermatic canal. Another specimen also illustrates occlusion of the right spermatic canal, but probably of recent date, because the seminal vesicle does not appear to have undergone the shriveling process.

Interstitial is generally secondary to parenchymatous phlegmasia of the vesicle and is characterized by plastic infiltration of the intertubular connective tissue. Suppuration may take place primarily in the intertubular connective tissue, but this can occur only from the destructive action of a sudden and superabundant exudate. Generally the exudate becomes imperfectly organized, undergoes sclerous degeneration, and the vesicle shrivels. Sometimes the exudate is better organized and the vesicle remains large and is some-

what indurated. Several of the specimens presented illustrate this point and show both vesicles to be considerably enlarged, hard, and filled with large sympexia. The shriveled condition of the seminal vesicles is common in cases of prostatic enlargement demanding frequent evacuative catheterism of the bladder for several years, the patients having had repeated attacks of orchitis with involvement of both vesicles.

Of sixty dissections of the seminal vesicles made in cases of prostatic enlargement, three fourths of these vesicles were shriveled and hard. The remainder, though not diminished in size, were more or less indurated. In a few instances they were enlarged, and in one case they were cancerous. In a specimen recently dissected, both vesicles were found reduced to less than half of their normal size and were nearly as hard as cartilage. A longitudinal incision made into the left vesicle showed the lumen of its tube to be reduced to about two millimetres in diameter, except at the posterior extremity of the vesicle, where its walls were attenuated, translucent, and expanded into a cyst containing three grammes of limpid fluid. The right vesicle, which was not incised, presented the same external appearances as the left. The prostate was considerably increased in size, very hard, and had for several years impeded urination. The patient died in consequence of pyelonephritis.

The symptoms of acute gonocystitis so far observed are: Almost constant painful erections of the penis; frequent and painful ejaculations of semen mixed with pus and blood, until the ejaculatory duct is occluded, when spermatic colic occurs; pain extending along the urethra to the extremity of the penis (this, however, is an index of coexistent trachelocystitis); difficult, painful, and frequent urination; burning pain in the perinæum, at the anus, and at the lower end of the rectum; a sense of tension in the rectum; rectal tenesmus; and very painful defecation. Rigors and febrile reaction, and throbbing pains in the rectum indicate suppuration. Retention of urine sometimes occurs in case of great tumefaction of one or both vesicles.

The diagnosis of acute gonocystitis is arrived at by an analysis of the symptoms, by digital examination through the rectum, and by intra-urethral instrumental exploration. The digital examination reveals more or less tumefaction, heat, and tenderness in the region of the vesicles on one or both sides as the case may be. If the swelling is in the form of a single, hard, oblong tumor extending from the base of the prostate upward, backward, and outward, the presumption is that the phlegmasic process has not extended beyond the proper capsule of one seminal vesicle. If, however, there is a diffuse, doughy swelling extending beyond the median line, it is likely that both vesicles are involved, that perforation of their walls has taken place, and that the ambient connective tissue is infiltrated. When one vesicle only is involved in suppuration together with the pre-rectal connective tissue, the pus sometimes points in the direction of the ischio-rectal fossa. In such cases the digital examination indicates the lateral deviation of the abscess. The instrumental urethral exploration should be made first by introducing a gum catheter with the object of emptying the bladder. This done, a moderate-sized rectangular steel

sound should be carefully introduced. Though the first catheterism may have given some pain, the moment the sound reaches and distends the prostatic region of the urethra and passes over the veru montanum the most acute burning pain is experienced and continues as long as the instrument is retained. Without loss of time a finger should be passed into the rectum and pressure made along the median line of the prostate in order to break up and cause the expulsion of a sympexion which may be plugging the ejaculatory duct. Several of the symptoms being common to acute prostatitis, the rectal and urethral explorations are necessary to distinguish acute gynecystitis from acute prostatitis. The connections of the ejaculatory ducts with the urethra, the seminal vesicles, and the spermatic canals explain how gynecystitis and orchitis may occur at the same time. But, as before stated, the phenomena of the orchitis are generally such as to mask those of the gynecystitis. It is therefore wise in most cases of orchitis to make by the rectum a digital exploration of the seminal vesicles, which, if found tender to pressure, swollen, and hot, should be treated accordingly.

*In the treatment of the acute types of gynecystitis* the chief indication is to prevent interstitial suppuration. For this end a similar course to that pursued in acute prostatitis should be adopted. After thoroughly cleansing the rectum, three or four leeches may be applied to its mucous membrane in the region of the affected vesicle, with the aid of a tube such as that recommended by Dr. Hughes, of Dublin, for leeching in acute prostatitis. When the well-gorged leeches have cast themselves away, irrigation of the rectum with warm water should be made until it is judged that a sufficient quantity of blood has been lost. If it is found impracticable to leech by way of the rectum, a greater number of leeches—ten or twelve—may be applied to the anal and perineal regions. Enough blood will thus be drawn to unload the congested prerectal plexus of veins. As soon as possible after either of these modes of local depletion, the lower end of the rectum should be packed with cracked ice. When the ice melts, the water is allowed to flow out, while the anus is stretched open for the introduction of more ice suppositories, a process to be repeated at least every hour while the patient is awake. These frequent applications of ice should be continued two or three days, and longer if necessary.

This antiphlogistic treatment is valuable only during the period of increase or of stasis of the phlegmasia. Begun later, it is apt to be worse than useless. If, however, it is employed at the right time and faithfully carried out, much suffering is prevented, and resolution is likely to be hastened. Otherwise suppuration occurs, and, to prevent the pus from finding an outlet which may be dangerous to the patient, the sooner a free exit is artificially given to this pus the better for his safety. The particular process of relief should be adapted to the condition of the individual and to the extent of the abscess. When it is ascertained by digital exploration that the abscess is not large but well defined on one side or the other of the median line, the presumption is that the pus has not passed beyond the boundary of the proper fibrous capsule of one vesicle. In

such a case aspiration through the rectal walls is indicated. The parts should be brought to view by means of a Sims speculum, and a slightly curved aspirating needle, not less than two millimetres in caliber, should be thrust into the abscess and the cavity quickly emptied and then well irrigated with a warm sublimate solution (one to five thousand). A single aspiration may suffice; but in case the cavity refills, the aspiration and irrigation should be repeated. If from superacute phlegmasia there is reason to believe that much necrosis of the tissues has occurred, or if the pus has broken through all barriers and has already infiltrated the prerectal connective tissue, a Sims speculum should be introduced, and a free incision through the wall of the rectum should be made into the abscess, whose cavity should be well disinfected and lightly packed with a tent of antiseptic gauze. This dressing to be renewed every day. Whenever the abscess is large, and this is generally the case when it has been of very slow development, almost chronic, it is likely to point laterally toward the ischio-rectal fossa. In that case it should be reached by the way of the perinaeum, as suggested by Mr. Lloyd. The incision may be central or lateral, and directed so as to avoid the urethra and rectum. In case of doubt—that is to say, in case, from the extent of the purulent collection, there is a suspicion that both vesicles are affected—it is wise to make a crescentic incision three quarters of an inch in front of the anal margin and deepen the cut by careful dissection between the rectum and prostate, care being taken to avoid wounding the urethra. After giving free vent to the pus, the abscess cavity should be disinfected and very loosely packed with a tent of antiseptic gauze, so that the healing process may begin at the bottom of the cavity.

**CHRONIC GONECYSTITIS.**—Though acute gynecystitis often resolves without suppuration, it becomes chronic in a considerable proportion of cases, while in a great majority of instances chronic gynecystitis begins independently of the acute types.

*The common causes* of chronic gynecystitis are venereal excesses and masturbation, both giving rise to chronic urethritis, which is the immediate cause.

*The symptoms* of the chronic are similar to those of the acute type, but the suffering is less, and there is no febrile reaction. One of the most constant symptoms is a burning, itching sensation in the perinaeum, anus, and rectum, such as occurs in the acute type, but not so intense, though continuous in some cases, and very harassing month after month and year after year. Another phenomenon is painful spasmodic contraction of the anal sphincter. When a seminal vesicle is in a chronic phlegmasiac state, there is often a persistent urethral discharge consisting of pus, a little blood, some epithelium, and a few dead spermatozooids.

Spermatic colic is another, though not very frequent, symptom of chronic gynecystitis. It is due to the lodgment of a large sympexion in the ejaculatory duct and consequent retention of semen, mucus, and pus in the seminal vesicle.

Pus intimately mixed with semen is regarded by Chris-

tian Smith as a pathognomonic symptom of chronic phlegmasia of the seminal vesicles. The only means, says Dr. Smith, of ascertaining the source of this pus is by examining the semen that has dried on the patient's linen after coitus or after an involuntary pollution. "The stain made upon linen by normal semen is of a uniform grayish-white with a darker border, which never contains any element of yellow, while in case of phlegmasia of the seminal tract the dried stain presents a more or less yellow coloring, either throughout or at the border, which is the most highly colored. When the pus originates in the urethral or prostatic crypts, its mixture is never so intimate as in the first case, and the yellow coloring shows itself in minute zones or in disseminated spots upon the gray stain."

*Progress.*—When, in the chronic type of gonocystitis, the ejaculatory duct becomes occluded, the secretions gradually accumulate and cause ectasia of the vesicle and sometimes also of the spermatic canal. Such cases are of rare occurrence, and their symptoms are not easily interpreted.

Dr. Nathan R. Smith, of Baltimore, reported in the *Lancet*, 1872, vol. ii, p. 558, with the title of Hydrocele of the Seminal Vesicle, a case of cyst of the left seminal vesicle which filled the pelvis and extended into the abdominal cavity to a point above the umbilicus, and was at first mistaken for retention of urine. The cyst was tapped by the rectum and ten pints of a brown serous fluid were drawn. In four weeks the cyst filled again and was again tapped. This time it did not refill. Reference to this case is made by Mr. Lloyd.

A remarkable example of ectasia of the spermatic canal is recorded by Troussel-Delvincourt in the *Nouveau journal de médecine*, October, 1820. The right spermatic canal formed a cylinder measuring nearly two inches in diameter, soft, smooth, filled with a thick, pulpy, yellow material, similar to that of softened tubercle. The seminal vesicles contained a similar but less consistent material.

These two are very exceptional cases, the ectasia rarely exceeding twice the normal caliber of the vesicle and canal, as shown by the specimens exhibited.

*Subacute and chronic phlegmasia* sometimes end in calcareous infiltration of one or both vesicles and spermatic canals. Among the specimens exhibited is a good illustration of calcareous infiltration of the spermatic canals.

Since *phlegmasia of the spermatic canal* is ordinarily associated with gonocystitis, sterility is one of the sequels of the chronic type when both sides are affected, the spermatozooids being destroyed by the abnormal secretions of the spermatic canals and seminal vesicles. When the two spermatic canals or the two ejaculatory ducts are permanently occluded, impotency is the result, erection of the penis being imperfect and sexual desire finally extinct.

In elderly men, as seen by the results of the dissection of sixty pairs of seminal vesicles, there is often shriveling of the vesicles from chronic phlegmasia. In younger subjects the chronic phlegmasia is generally confined to the mucous membrane and the vesicles are more likely to be dilated and filled with large sympexia. In several of the thirty-four dissections first mentioned a sympexion was found blocking the ejaculatory duct. In these younger

subjects the symptoms are ordinarily distinct, while in elderly persons they are frequently wanting, and the altered condition of the vesicles is ascertained only at the necropsy.

*The treatment of chronic gonocystitis* should consist in endeavors to cure the existing chronic urethritis, and in emptying the distended vesicle every day by pressure with the finger passed into the rectum. This may be followed by very warm enemata and the occasional use of rectal suppositories containing half a grain of belladonna extract and one grain of opium. From time to time the passage of a steel sound and digital pressure thereon through the rectum should be resorted to for the purpose of effecting the expulsion of sympexia from the ejaculatory duct. The process should be employed as well for purposes of diagnosis as for relief at the same time, the extraction of the sympexion allowing the distended vesicle to be emptied and relieving a painful spermatic colic.

TRACHELOCYSTITIS—phlegmasia of the neck of the bladder—having already been examined, needs now only to be named.

PYELITIS AND NEPHRITIS very rarely occur in consequence of acute urethritis and are generally indirectly caused by urethritis—that is to say, they are among the ill effects of imprudent treatment, such as the long continuance of balsamics in excessive doses, particularly copaiba balsam, which has been known to cause acute parenchymatous nephritis and pyelitis, and finally chronic diffuse nephritis with albuminuria. Balsamics can not be too cautiously employed in the treatment of urethritis. The use of copaiba, or any other balsamic, should be discontinued, and on no account resumed, in the cases which show their susceptibility to its toxic effects by a profuse exanthem, an articularia, or a papular eruption on the face and body. These are the cases which are likely to be complicated with nephritis. Some observers think they have detected a mild subacute pyelitis in the majority of cases of urethritis, whether acute or chronic. May not this pyelitis be owing to the heroic treatment too often employed in the management of the several types of urethritis?

SEPTICEMIA AND PYOSAPRÆMIA very seldom occur as consequences of urethritis.

*Septicæmia*—putrid infection of the blood—is due to the evolution of ptomaines or of leucomaines, the first being the product of bacterial ferments developed in parts of the body that have become putrescent from injury, the second indigenous to the body and evolved in disease independently of bacterial ferments. Septicæmia consequent upon urethritis is probably sometimes a leucomainal intoxication, and is manifested by a violent rigor with much constitutional disturbance in some cases of superacute urethritis. This intoxication may be so profound as to be uncontrollable. In all cases there is constitutional disturbance, but in the majority it is of comparatively minor intensity. The poison is apparently less virulent, but this lesser virulence is rather in degree than in kind. Nevertheless, the poison is very gradually eliminated, and the suf-

ferer—pale, emaciated, and feeble—makes a slow, lingering recovery, convalescence requiring six or eight weeks. In the first-named type of cases the indication is to insure rapid elimination of the poison. To that end free catharsis, diuresis, and diaphoresis should be promptly established, and during the action of the remedies employed the vital powers should be sustained by stimulants and reconstituents. If these means are successful, the case may be managed as in the second type, which permits the more deliberate selection of agents likely to safely expedite the elimination of the poison. The cathartics should be replaced by aperients, and the diaphoretics and diuretics should be mild, but continued two or three weeks. Five grains of chloride of ammonium thrice daily, and ten minims of tincture of chloride of iron, both largely diluted, should be given from the beginning to the end of convalescence. The diet should be mild, but nourishing and easily digested. Milk at first, then more substantial food, and generous wines.

*Pyosapræmia*—putrid pus infection of the blood—differs from septicæmia clinically and pathically. Septicæmia often occurs before the formation of pus, while pyosapræmia may not be manifested until several weeks after the infliction of a wound or the formation of an abscess. In septicæmia there are generally no secondary abscesses. In pyosapræmia, infective thrombi swarming with micro-organisms are found in the neighboring veins and carried into the circulation to cause multiple abscesses, sometimes in the viscera, sometimes in other parts of the body distant from the point of injury. These thrombi contain great numbers of staphylococci and streptococci. The favorable cases are generally those in which the viscera have escaped contamination, and the thrombi have lodged in muscles or in superficial connective tissue.

Pyosapræmia occurs as a consequence of urethritis in case of a solution of continuity, as occurs from "breaking the chordec," or from some other injury, or in case of abscess in any part of the urogenital tract. In these two circumstances infective thrombi are formed in the ambient veins and their migration begins. Septicæmia is manifested by one violent rigor and much febrile reaction, while pyosapræmia is characterized by recurring slight rigors of short duration, with less febrile reaction than septicæmia. When death occurs in consequence of acute urethritis there is either septicæmia or pyosapræmia. It is almost impossible to ascertain the percentage of mortality from these causes, for such cases are very seldom reported.

A few years ago, at Bellevue Hospital, a death occurred, which may be regarded as an excellent illustration of pyosapræmia originating from urethritis. The subject of this affection was a boy, seventeen years of age, who was suffering from superacute urethritis and a consequent perineal abscess. He had slight recurring rigors and other signs of profound pyosapræmia, and died three weeks after his admission to the hospital.

RHEUMATISM as an occasional consequence of urethritis, occurring in a little less than two per cent. of all cases, was first specialized in the latter part of the last century (1781)

by Swediaur and by Selle. Swediaur's chapter on the subject is short, bears the title of *Arthrocele, Gonocele, or Blennorrhagic Swelling of the Knee*, and begins as follows: "A very considerable swelling of the knee, sometimes of both knees and the heel at once, attended by excruciating pains in the joint, sometimes occurs in men after a blennorrhagia. These pains, accompanied by more or less symptomatic fever, continue for two or three weeks, and gradually go off, leaving a stiffness in the joint, which lasts for many months. The disease particularly affects young men who, after a debauch, have been infected with blennorrhagia, with which it seems to be intimately connected. . . . It is not very uncommon, for in the course of my practice I have seen six or eight cases, each of which came on about the eighth or sixth day of the blennorrhagia, and in every instance the discharge from the urethra was either sensibly diminished or totally suppressed. For want of sufficient observation, I have not been able to determine the character of this disease; but in all the cases which have come within my knowledge the disease appeared to partake of the character of gout, with this exception, that all the persons were about the age of twenty-three or thirty, that the color of the skin was not changed, and that the swelling bore handling without exciting pain. The swelling gradually disappears by the free use of diluting drinks and by frictions with the ammoniacal liniment. . . ." This laconic description contains nearly all that is now known of the gross pathology, ætiology, diagnosis, and therapeutics of the affection. Additions, but no subtractions, have been made to Swediaur's chapter by more than three hundred writers on the subject since his time.

The character of these additions is far from exhibiting a general consensus of views respecting the nature of "urethral rheumatism," which still remains unexplained.

A synoptical presentation of a few of these diverse views will answer the purpose of this conference.

Swedianr, Lagneau, and Cullerier attributed "urethral rheumatism" to metastasis, and the affection was afterward treated in accordance with that hypothesis.

There are others who thought "urethral rheumatism" to be the effect of the cubeb and copaiba treatment of urethritis. Still others, among whom are several French, English, and American writers, have regarded "urethral rheumatism" as one of the effects of pyosapræmia.

Féréol spoke of a blennorrhagic diathesis analogous to, but not identical with, the syphilitic diathesis, and of an acquired diathesis corresponding to an individual predisposition, which individual predisposition Fournier admits.

Tixier, who has written an extended essay on the subject, also believes in a blennorrhagic diathesis.

Bonnière asserts that arthropathy and blennorrhagia are nothing more than the expression of the same vice—the rheumatic diathesis.

They believed that the so-called blennorrhagic arthritis is merely coincident with urethritis, without being related to it in the slightest degree.

It has been noticed that individuals suffering from "urethral rheumatism" are often affected with eczematous and other cutaneous eruptions.

Ample experience has shown that simple non-virulent urethritis is as liable to be accompanied by "urethral rheumatism" as the virulent species.

While Fournier, the highest authority on the subject, believes in the existence of a "blennorrhagic rheumatism," he admits that rheumatism arises also from non-venereal urethral phlegmasia, and for that reason gave it the name of "urethral rheumatism," which, after all, is no better than gonorrhœal, blennorrhagic, or genital rheumatism, and in reality means simply rheumatism of the urethra.

These views, the outcome of one hundred years of discussion of the question of rheumatism occurring among individuals suffering from genital phlegmasia, are all inconclusive, for they fail to explain the true nature of the affection, and seem to relate more to its phenomena than its essence.

Of the many arguments made to establish a distinctness of "genital rheumatism" from common rheumatism, not one seems to adduce evidence sufficient to warrant such specialization. Nor do the contrary arguments seem better founded. A critical examination of both sides of the question brings into bold relief their weak as well as their strong points. Both strive to prove too much and thereby injure their cause. Those who wish to specialize "genital rheumatism" make urethritis its essential cause, and assert that it has few if any of the characters of common rheumatism, though they acknowledge that it is sometimes acute, the great majority of cases being subacute, and often chronic and affecting the knee. They further acknowledge that it affects parts which are just as commonly involved in ordinary rheumatism, and some of the contestants even point out sequelæ which belong to ordinary rheumatism. They thus enumerate the parts affected in "genital rheumatism," arthritis, hydrarthrosis, and arthralgia of the large and small joints, bursitis, sciatica, myalgia, ophthalmia, and affections of the heart, of the membranes of the brain, spinal cord, etc. Those who take the contrary side say that the rheumatic manifestations are merely coincident and do not bear the slightest relation to genital phlegmasia.

It seems that the extreme views of both contesting sides should be rejected, because the assertion that genital phlegmasia is the essential cause of the rheumatism is not proved, and because it is not proved that the rheumatism bears no relation to the genital phlegmasia.

Is it not likely that the affection is ordinarily a subacute rheumatism, excited in a vulnerable subject by the genital phlegmasia, just as it might be excited by any other phlegmasia, and that it therefore does bear a distinct and close relation to its exciting cause?

It is hoped that bio-chemists and patho-histologists will re-examine the lactic-acid and other questions, and ere long enlighten the profession respecting the essence of what is called rheumatism, and help to determine if its association with genital phlegmasia is or is not a coincidence.

Whatever may be the nature of the ailment commonly styled "gonorrhœal rheumatism," its treatment differs little if at all from that of acute or that of subacute rheumatism.

## GALLACETOPHENONE, A NEW DERMATO-THERAPEUTIC AGENT.

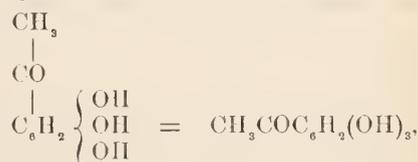

BY HERMANN GOLDENBERG, M. D.

THE object of this article is to introduce and recommend a new remedy for psoriasis and similar skin diseases, with the hope that it will not share the fate which falls to the lot of so many new drugs.

In the September number of the *Therapeutische Monatshefte* Dr. L. von Rekowski recommends "gallacetophenone" (I suppose erroneously spelled) as a substitute for pyrogallie acid. The commercial name of this new drug is "alizerine-yellow C." It is prepared by treating pyrogallie acid with acetic acid in the presence of chloride of zinc. It is a yellowish powder which readily crystallizes in yellowish needles, scarcely soluble in cold water, easily soluble in hot water, alcohol, ether, and glycerin.

Messrs. William Piekhardt & Kutroff, of New York, the general agents of the "Badische Anilin- und Sodafabrik," were kind enough to supply me with a quantity such as is used as a dye-stuff, which was converted into pure gallacetophenone by my friend Dr. H. Schweitzer.

Gallacetophenone has the formula—

and is pyrogallie acid in which  $\text{CH}_3\text{CO}$  are substituted for H. It differs from pyrogallie acid in that it is oxidized in alkaline solutions so slowly that its reducing abilities are much less.

It is well known that pyrogallie acid is by no means a harmless drug. After its introduction into dermatological practice Neisser lost a patient after one application. The patient died on the third day with symptoms of intoxication. Vidal has likewise reported the death of a patient, eighteen years old, who had used a ten-per-cent. pyrogallie ointment for two weeks. This poisonous effect of pyrogallie acid is to be attributed to the great readiness with which it is oxidized in alkaline solutions (being so intensely reducing).

The new drug does not possess this quality and is absolutely harmless, as has been proved by experiments on animals.

It displays strong antiseptic qualities. A one-per-cent. solution added to chopped meat prevented its becoming putrid for twenty-one days, and destroyed the *Streptococcus aureus* within twenty-four hours.

Since the middle of October I have employed gallacetophenone, both in private and in dispensary practice, on at least thirty patients suffering from various skin diseases.

On account of its resemblance to pyrogallie acid, it seemed to be indicated in psoriasis. I have been so much more inclined to use it in that disease, since von Rekowski, who tried it in a few cases only, maintains "that the effect of this new preparation (used as a ten-per-cent. ointment) is noticed within twelve hours."

Altogether, I have thus employed it in twelve cases of psoriasis—in all of them with good results. Within a few days the patches became paler and thinner, the desquamation ceased or became less, and involution took place in the centers. Usually after the lapse of from ten to twelve days only a slight hyperæmia was left. Within from two to three weeks the patches disappeared entirely without leaving any pigmentation.

A ten-per-cent. ointment did not produce any marked irritation or discolor the skin. It stains the clothes slightly yellowish, much less than pyrogallic acid or chrysarobin. I do not wish to go into the details of the cases, but would like to state that in a case of psoriasis of the face and scalp it really acted like a specific. The eruption, which was quite profuse, disappeared within five days. A ten-per-cent. ointment was applied twice daily. There was no other treatment.

Another patient with a universal psoriasis of sixteen years' standing, who applied to my department at the Mount Sinai Dispensary for some other trouble, was induced to use a ten-per-cent. salve of gallacetophenone for the forehead and scalp, which were thickly covered with psoriatic patches. When he returned, two weeks later, there was nothing left but a pigmentation of the forehead, while the psoriasis of the body which had not been treated was *in statu quo ante*.

My friend Dr. G. T. Elliot has, at my request, used gallacetophenone on a patient with psoriasis of eight years' standing, distributed over the trunk, knees, elbows, scalp, and face in patches of various sizes. The case had been under treatment the whole time and had proved exceedingly rebellious. Arsenic caused an increase of inflammatory symptoms. Pyrogallic acid had been used with but moderate success. Chrysarobin did well, if used persistently. At the time (November 21st) when the use of a ten per-cent. gallacetophenone ointment was begun, the patches were bright red, burning, and with abundant desquamation. A week later the patches were paler and breaking up into small papules. The centers had undergone involution and the desquamation was very little. Under the further use the improvement continued. Dr. Elliot concludes his report with the following words: "From this slight experience, gallacetophenone appears to me to promise to be the most satisfactory local remedy for psoriasis and superior to all others. It produces no inflammatory reaction or pigmentation, but seems to influence immediately the lesions."

From my experience, I feel justified in recommending gallacetophenone as an excellent remedy for psoriasis, for it acts in some cases more promptly than chrysarobin—in all the cases which I have treated, as well if not better than the other remedies at our disposal. As it is harmless and does not discolor the skin or hairs, I hope it will be found to be one of the best local remedies for psoriasis of the body, face, and scalp.

My results in a number of cases of eczema psoriaticiforme and seborrhoicum have been so gratifying and encouraging that I should like to include these affections in its field of usefulness.

Messrs. Breyer and Schweitzer, consulting chemists, 159 Front Street, will furnish the chemically pure gallacetophenone to physician and druggist.

THE  
NEW YORK MEDICAL JOURNAL,  
*A Weekly Review of Medicine.*

Published by  
D APPLETON & Co.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, FEBRUARY 6, 1892

THE AMBULANCE SURGEONS OF NEW YORK.

It rarely seems necessary or desirable to take notice of the misapprehensions or misrepresentations of medical matters in the public journals. They usually carry, for professional readers at least, such evident marks of error that they are their own antidote. But a recent occurrence has been so grossly misrepresented, and such vile assaults have been made upon innocent persons, that it becomes a plain duty to state the facts and to take an open stand in support of our fellows.

The story, as told, is that between six o'clock in the evening and eight o'clock the next morning an ambulance was called three times from one of our hospitals to a man who had had a fall; that each time the ambulance surgeon refused to take the man, giving as the reason that he was drunk; that the man was then taken to the Tombs and sent thence to Bellevue Hospital, where he died twelve hours later; and that the autopsy showed that he had died of a fractured skull.

The facts, very briefly stated, are these: The man, a sailor, had been drinking at the time of his fall; when first examined he showed no other injury than a bruise of the forehead and an abrasion on the nose; he was not only conscious, but violently abusive; the ambulance surgeon, who had a woman with a broken leg in his ambulance, told the man's employers to notify the police to take charge of him. The second call, three hours later, was sent from the station-house because the doorman noticed fresh blood about the man's mouth. The ambulance surgeon washed the man's face, wiped out his nose and mouth, and found that the blood came in part from a broken tooth and in part from the abrasion on the nose. During his stay of twenty-five minutes he was steadily cursed by the patient, who actively opposed his ministrations. The occasion of the third call, at eight o'clock the next morning, was the patient's allegation that his leg was painful and that he could not walk to the police court. The surgeon was asked for an opinion as to the leg. Again he made a careful examination, spending nearly an hour in the station-house, for the man was still intractable and resisted examination. The surgeon pronounced the leg sound.

The man was then taken to the Tombs, and thence sent as a vagrant to Bellevue Hospital, where he was placed in the "alcoholic" cells. About three hours after his admission he became unconscious, and was transferred to the wards, where an exploratory incision was made and a stellate fracture of the frontal bone, without depression, found. He died during the night. The post-mortem examination, which was limited to the head, disclosed the fracture that had been found before death, and in addition fissures running across the orbital plates and the mid-

dle fossa of the skull. There had been no intracranial hæmorrhage and no laceration of the dura or brain. The deputy coroner who made the autopsy stated at the inquest that the fracture could not have been recognized without an incision, and that none of the usual signs of fracture were present.

It is easy to be wise after the event; it is easy to say that the man should have been taken to the hospital, drunk or sober; but who would have taken a different course from that taken by the ambulance surgeon, on the facts and the information obtainable at the time? The coroner's jury recommended that all drunken men who had met with any injury should be taken to a hospital, a recommendation which not only is utterly impracticable and impertinent, but which, if the attempt should be made to carry it out, would cause greater scandal and noisier remonstrances than even the occasional failure to recognize a fractured skull.

Advantage has been taken of this occurrence to abuse not only the ambulance surgeons of the hospital concerned in it, but the ambulance surgeons of New York as a class; they have been held up to the scorn and reprobation of the community. It is high time that a word should be spoken, and loudly spoken, in behalf of the young men in our hospitals. A more meritorious, intelligent, hard-working, conscientious set of young men can not be found. They work hard and long to obtain their positions, which they do by giving proof of superior intelligence and acquirements, and they work hard and long while they hold them, in order the better to fit themselves for the practice of their profession. In a word, they are the flower of the younger men, and in a few years they will stand fully ahead of the best of the older ones. If they can not do the work well, it can not be done well. But, notwithstanding all that has been said, notwithstanding their liability to error, and notwithstanding their inability to see what is invisible, and to touch what is intangible—an inability which they share with the rest of mankind—their work is well done. The superintendent of one of our largest hospitals, when recently asked by a reporter if the present system of ambulance service was satisfactory, replied that it was, and "eminently so." And in this opinion of an impartial, and necessarily even an exacting, superior we are confident that all who have personal knowledge of the matter will heartily concur.

MINOR PARAGRAPHS.

THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

THE eighty-sixth annual meeting was held in Albany this week. The programme was long and sufficiently attractive, but many of those who were expected to read papers, on the first day, at least, were absent. Especially was there on that day an absence of many of the well-known New York men whose custom it has been for many years to be present. Of the papers that were presented it can fairly be said that there has been no deterioration as to quality in comparison with the experience of previous years, and we can infer from this fact that the work done by the members of the society is still such as would be creditable to any meeting of this kind. We wish to note particularly the unusual excellence of the president's

address. It was broad and scholarly, embracing in its scope subjects that are of interest to every member of the profession who has regard for its well-being and usefulness.

COMPARATIVE ANATOMY AND ZOOLOGY FOR MEDICAL STUDENTS.

WE have received a pamphlet containing two addresses by Dr. Harrison Allen, of Philadelphia, advocating the teaching of comparative anatomy as a part of the medical curriculum, and on the teaching of anatomy to advanced medical students. Dr. Allen has recently reassumed the chair of zoology and comparative anatomy in the University of Pennsylvania. The object of the papers is to excite an interest in the study of zoology and comparative anatomy by medical students. The broader the learning and greater the erudition the better the physician, and we commend most highly Dr. Allen's efforts to introduce these studies into the medical curriculum in this country. Dr. Allen is a competent and conscientious instructor, and those who come under his teaching will have advantages which can be obtained in few if any other schools.

THE HARRIS CASE.

IN view of the possibility of a new trial of Carlyle W. Harris, who on Tuesday was convicted of having murdered his wife by morphine poisoning, it would be improper for us to comment on the character of the medical testimony in the case. We think it proper, however, to express our sense of the excellence of the Recorder's charge to the jury, and to congratulate the medical profession on the probability that Harris will never be able to enter its ranks, for, whatever disposition may finally be made of him with reference to the crime for which he is awaiting sentence, he is branded as a thoroughly bad man.

ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending February 2, 1892:

DISEASES.	Week ending Jan. 26.		Week ending Feb. 2.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	8	2	11	2
Scarlet fever.....	211	26	192	19
Cerebro-spinal meningitis.....	2	3	2	1
Measles.....	128	9	137	12
Diphtheria.....	122	38	87	30
Small-pox.....	11	0	5	0
Erysipelas.....	5	0	0	0
Varicella.....	18	0	0	0
Pertussis.....	0	2	0	0
Leprosy.....	1	0	0	0

**The Cartwright Lectures of the Alumni Association of the College of Physicians and Surgeons** will be delivered at the Academy of Medicine on the 12th, 19th, and 26th inst., at 8 P. M., by Professor Henry F. Osborn, of Columbia College. The general title of the lectures is Present Problems in Evolution and Heredity. The purpose of these lectures is to discuss fairly the theory of the transmission of acquired characters (effects of habit, use, and disease) and to show how it simplifies the problem of evolution and renders much more difficult the problem of heredity. The *evolution of man* as going on at the present time is discussed in the first lecture, in order to show that this is following various changes of habit connected with civilization and that each organ in the body has a distinct line of evolution of its own. The laws of variation (anomalies) and reversion are thus brought out as part of the elements of a complete heredity theory. The second lecture traces the *history of the theory of heredity* as considered by Lamarck, Darwin, Galton, and Weismann. The advantage of Weismann's continuity of the

germ-plasm idea as an explanation of the phenomena of repetition and reversion are contrasted with the difficulties in which evolution by natural selection only involves us. On the other hand, it is shown how far we are at present from a heredity theory which will explain the transmission of the effects of use and disuse. In the third lecture the discussion is turned upon the ova and spermatozooids, the origin of sex, and the meaning of the metamorphoses in these cells in relation to heredity. The studies of Balfour, Van Beneden, Hertwig, Boverie, and Weismann are reviewed to show what portion of the cell bears the hereditary characters and how they reach various portions of the body.

**The Harlem Medical Association.**—The programme for the meeting of Wednesday evening, the 3d inst., included a paper on The Treatment of External Injuries to the Eye, by Dr. G. H. Cocks; also the presentation of a patient with an aneurysm of the supra-orbital artery, by Dr. O'Brien.

**The New York Surgical Society.**—Dr. Robert H. M. Dawbarn has been elected a member. At the next meeting, to be held at the Academy of Medicine, on Wednesday evening, the 10th inst., Dr. V. P. Gibney will read a paper on The Prognosis in Compression Myelitis from Pott's Disease, to be followed by a discussion on its surgical treatment.

**The Lenox Medical and Surgical Society.**—At a meeting to be held on Monday evening, the 8th inst., Dr. J. Blake White will read a paper entitled Pneumonotomy Twice on the Same Patient for the Relief of Tubercular Abscess of the Lung; Recovery.

**The Society of Medical Jurisprudence.**—At a meeting to be held on Monday evening, the 8th inst., the Hon. Austin Abbott, LL. D., is to read a paper entitled Physicians on the Witness Stand.

**The New York State Medical Association.**—The eighth annual meeting of the Fifth District Branch will be held in Brooklyn on Tuesday, May 24, 1892. All fellows desiring to read papers will please notify the secretary, Dr. E. H. Squibb, P. O. box 94, Brooklyn.

**The Death of Sir Morell Mackenzie, of London,** the well-known laryngologist, is announced as having taken place on Wednesday, the 3d inst. He was fifty-four years old.

**Changes of Address.**—Dr. J. T. Clegg, from Siloam Springs to No. 121 Thomas Avenue, Dallas, Texas; Dr. Wilbur P. Marple, to No. 29 West Thirty-first Street; Dr. Albert C. Stannard, to No. 119 West Thirty-fourth Street.

#### Society Meetings for the Coming Week:

**MONDAY, February 8th:** New York Academy of Medicine (Section in General Surgery); New York Ophthalmological Society (private); New York Medico-historical Society (private—anniversary); New York Academy of Sciences (Section in Chemistry and Technology); Lenox Medical and Surgical Society (private); Boston Society for Medical Improvement; Gynecological Society of Boston; Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private); Baltimore Medical Association.

**TUESDAY, February 9th:** New York Medical Union (private); Medical Societies of the Counties of Delaware (semi-annual) and Rensselaer, N. Y.; Kings County Medical Association; Newark, N. J., and Trenton (private), N. J., Medical Associations; Baltimore Gynecological and Obstetrical Society.

**WEDNESDAY, February 10th:** New York Surgical Society; New York Pathological Society; American Microscopical Society of the City of New York; Medical Society of the County of Albany; Pittsfield, Mass., Medical Association (private); Franklin, Mass., District Medical Society (quarterly—Greenfield); Philadelphia County Medical Society.

**THURSDAY, February 11th:** New York Laryngological Society; New York Academy of Medicine (Section in Pediatrics); Society of Medical Jurisprudence and State Medicine; Brooklyn Pathological Society; Medical Society of the County of Cayuga; South Boston, Medical Mass., Club (private); Pathological Society of Philadelphia.

**FRIDAY, February 12th:** Yorkville Medical Association (private); Medical Society of the Town of Saugerties, N. Y.; German Medical Society of Brooklyn.

**SATURDAY, February 13th:** Obstetrical Society of Boston (private).

## Proceedings of Societies.

### NEW YORK SURGICAL SOCIETY.

*Meeting of October 28, 1891.*

The President, Dr. CHARLES K. BRIDGON, is the Chair.

#### Rupture of the External Popliteal Nerve in Jumping.

—Dr. L. A. STIMSON presented a patient, twenty-seven years of age, who, on July 22, 1890, had ruptured the right external popliteal nerve during the effort of making a running jump; he fell at the end of the jump, but the fall was apparently the result, not the cause, of the rupture. When he rose there was pain and powerlessness below the knee. This patient had come to the speaker six months after the injury. There was then well-marked paralysis of the anterior and external groups of the muscles of the leg. Sensation was lost, in part, over the region supplied by branches of the cutaneous nerve. An incision was made behind the tendon of the biceps and the nerve was exposed. A mass of cicatricial tissue was found, and imbedded in this were the ruptured ends of the nerve, separated from each other about an inch. There was considerable loss in freeing the nerve, and its ends could not be approximated, sutured, and maintained in place without flexing the knee. The leg was accordingly dressed in this attitude and kept so until some time after healing of the wound. Dr. Starr had kindly seen the patient some six weeks after the operation, with a view of hastening, if possible, restoration of nerve function by electrical treatment. Before beginning this it was found that the reaction of degeneration was present in the tibialis anticus, while the peronei were still normal. The man received electrical treatment once a week for several months. It would be seen that his present condition was extremely satisfactory. The only symptom of the previous trouble was inability to raise the front part of the foot actively, though the foot did not drop at all in walking. The case was interesting as demonstrating that such an injury was possible as the result of jumping, and that an operation six months after the rupture of the nerve had given complete restoration of function for all practical purposes.

**Prolapse of the Rectum.**—Dr. F. KAMMERER showed a man, forty-five years old, upon whom he had operated for prolapse of the rectum according to Robert's modification of Diefenbach's method. The condition had existed since boyhood, and the patient had been subjected to a great deal of medical treatment. The rectum protruded for about three inches and a half from the anal orifice. When the bowel was replaced three fingers could with ease be introduced into the rectum through the much-relaxed sphincter. This, then, seemed to be a suitable case for a narrowing of the sphincter and lower part of the rectum. An incision was carried in the median line from the coccyx to the upper border of the sphincter, and then along the latter to both sides for about an inch. These incisions were now carried down to the rectum, separating the levator ani muscle, which was drawn to either side. Thus, a V-shaped portion of the posterior rectal wall was laid bare, the point of the V lying at the coccyx. This was excised, corresponding to about four inches of the rectal wall and an inch and a half of the sphincter. The walls of the rectum were first united by a running catgut suture, and then the remaining soft parts in a similar manner, but it was impossible, however, to entirely close that part of the wound cavity lying under the coccyx. This was packed with iodoform gauze. The sutures through the sphincter were strengthened by several deep silk-worm threads, externally as in Robert's case, and also in Bell's, both lately reported in the *Annals of Surgery*. A rectal fistula developed at the upper

angle of the wound, which was definitively closed only at the end of the third month after the operation. In the two other cases referred to it existed even a longer time. The result of operation, which was done about six months ago, had been a complete success; no recurrence of the prolapse, cessation of catarrh and ulceration of the rectum, and perfect control over feces and flatus.

**The Treatment of the Graver Forms of Pelvic Suppuration by the Intraperitoneal Iodoform Tampon.**—This was the title of a paper by the PRESIDENT. (See vol. liv, page 561.)

Dr. J. A. WYERN said that his experience with the iodoform tampon was limited to its use in some half-dozen cases, in which the operations had, for the most part, been done in the neighborhood of the vermiform appendix. The inflammatory processes were, of course, acute, and he could hardly call them abscesses, although in one case pus was present, but without limitation or encapsulation. The tampon had been invariably satisfactory when he had used it. In one instance a fecal fistula had been established, which had to be watched. In another case, in which he had removed the appendix twelve hours after the occurrence of perforation, he had come upon some fluid that looked like pus. The tampon was used and removed on the tenth day. He considered the iodoform tampon of great value in this class of cases, and believed that nothing else in the way of dressing gave such security.

Dr. PARKER SYMS thought that this was the only practical way of draining the abdominal cavity. In the cases treated by him he had removed the gauze on the fifth day and had found adhesions fully formed by this time.

The PRESIDENT said he now used the tampon in all cases of appendicitis where he found suppuration, and had in no instance regretted doing so, but he had regretted its omission in some cases.

**Cleft Palate.**—Dr. WYERN presented photographs of a case of cleft palate affecting the anterior half and not the soft parts in which there was complete lateral hare-lip. He said he had mentioned the case to call attention to a little point in correcting the deformity of the nose. When the bone was deficient on one side, the ala nasi resting upon the short side was always flattened out and reeeding. In order to correct this it was necessary to divide the upper maxilla on the short side, bring the anterior fragment forward to the level of the normal bone of the opposite side, and wire or pin it in this position until it united with the opposing maxilla. The ala nasi of both sides then rested on the same plane, and the deformity disappeared. When there was a projecting process of bone on one side, his practice was to crush this piece back and suture it in line with the short maxilla. In the case reported this operation had met with success.

Dr. STIMSON had obtained good results in cases of double cleft palate by dividing the premaxillary bone a little posteriorly and dropping it back to the line of the other two and fixing them in place. He thus saved all the lip and often some of the incisor teeth.

**Tubercular Pyelitis; Nephrectomy; Death** (reported by HENRY H. FORBES, M. D.)—The PRESIDENT showed a specimen and narrated the case of Joseph G., thirty-five years old, who had been admitted into his service in the Presbyterian Hospital on October 8th. There was no morbid family or personal history, save of a gonorrhœa three years before, the discharge lasting about a year, with bladder symptoms. The patient was suffering from pain in the right lumbar region, which radiated down the front of the thigh. It was present nearly all the time, and was sufficiently acute to interfere with sleep. Bimanual palpation detected tenderness and a tumor in the right costo-iliac region; the tumor had the configuration of the kid-

ney and was of considerable size. The diagnosis was made of pyelitis from infection ascending from the bladder, and the man was put upon treatment with fluid extract of iichi. The urine was acid, of a sp. gr. of 1.013, and contained traces of albumin, with twenty per cent. of pus, by volume. His condition remained unchanged, save that there was a slight diminution in the quantity of pus, but he had nightly elevations of temperature to between 103° and 104° F. He also complained of cough, and on questioning him it was found that he had suffered more or less from the same for some time. His chest was examined by the attending physician, who said there was slight consolidation at the left apex, which would not contra-indicate nephrectomy. It was done by a vertical incision. On opening the capsule, the surface of the enlarged kidney was found studded with tubercular foci, and the operator thought it better to remove the organ; so the pedicle was transfixed below the distended pelvis and securely tied with a heavy silk ligature. On making the section on the distal side of the ligature, the pelvis was found distended with pus. The specimen showed innumerable foci of tubercle, with deposits of the same character on the lining membrane of the pelvis. The patient never rallied, and died from the effects of shock forty hours after the operation. No examination of the body was permitted, which was much to be regretted, as the condition of the kidney made it not probable that its fellow was unsound.

**Tumor of the Thyroid Gland; Thyroidectomy; Recovery** (reported by HENRY H. FORBES, M. D.)—The PRESIDENT then showed another specimen and detailed the following history: Jane H., twenty-six years old, single, a domestic, Irish, was admitted into his service in the Presbyterian Hospital on September 29th. There was no morbid personal or family history, and her menstruation regular. A year and a half before, she had first noticed a lump in the front of the left side of the neck; it had not been painful or tender to the touch, but had caused considerable inconvenience in swallowing and impairment of phonation. She was also troubled with palpitation and giddiness. She had tried internal and external medication for some time without effect, and the rapid increase of the tumor of late had made her nervous and desirous of an operation. Examination revealed a tumor of about half the size of a billiard ball on the left side of the neck, moving with the trachea during the act of swallowing, and manifestly a part of the thyroid body; it felt solid and the case was believed to be one of struma hyperplastica fibrosa. On September 29th a long vertical incision was made just internal to the anterior border of the sternocleido-mastoid muscle, the tumor was exposed by a careful dissection, and, when exposed, was examined for fluctuation, which was not discovered. The superior thyroid artery was tied *en masse*. The inferior thyroid was isolated and tied. The isthmus was secured and the tumor removed with the loss of scarcely any blood. On section, it was found to contain a cyst, which probably could have been enucleated without sacrificing half of the gland. Recovery was uninterrupted and the patient was discharged, cured, on October 15th.

*Meeting of November 11, 1891.*

The President, Dr. CHARLES K. BRIDGON, in the Chair.

**Talipes Equino-varus.**—Dr. CHARLES MCBURNY showed a patient to illustrate a result after an extensive operation in a case of highly developed talipes equino-varus. The boy had for seven years previous to active surgical interference been under careful treatment at different institutions, and had undergone five operations, such as tenotomies, division of fascia, etc. This had gone on for seven years with the use of various forms of apparatus. Finally the conclusion was reached that nothing

more could be thus accomplished, and the patient had come under the speaker's care. At this time he was walking on the outer edge and dorsum of the feet. About a year ago the speaker had done a quite extensive cuneiform osteotomy upon each foot, which had enabled the feet to be drawn into very good position. Still, though the wounds healed well, yet after the splints were removed there was a slight degree of the original varus position. A second operation was therefore done six months subsequently. Another wedge was removed, almost on the line of the original operation, which allowed the deformity to be completely corrected. It would be seen that the result was very satisfactory, considering the condition which had previously existed. No mechanical apparatus had been used since the operation; the patient had now very useful feet. The more cuneiform osteotomy was done the more it would impress surgeons with its advantages over division of tendons and the long-continued use of apparatus in these aggravated cases.

**Dislocation of the Head of the Fibula.**—Dr. L. A. STIMSON presented a man, twenty-three years of age, who had been admitted into the House of Relief, Chambers Street, on the 26th of October, about an hour after an injury to the left leg. The patient, while hauling a heavy box, had slipped, and had then found himself unable to walk. There was no external evidence of violence, but a very marked prominence on the outer side of the upper part of the leg. Examination showed that the head of the fibula was dislocated outward and forward. All attempts at reduction by manipulation failed. The speaker therefore made an incision over the dislocated head of the fibula and then endeavored to pry the head of the bone back into place with a periosteum elevator. After further division of a strong fibrous layer running from the head of the fibula to the front of the tibia the reduction was effected. The wound united primarily, and the patient was discharged in a week. The injury was a very rare one, some eight or ten cases only having been chronicled. The speaker had already presented a similar injury to the society. As to the mechanism of the luxation, he was in doubt. It might arise through traction by the anterior and peroneal group of muscles, or possibly through the pressure of the astragalus against the lower end of the fibula.

The PRESIDENT, speaking of Dr. McBurney's case, thought that it was a success, and commended cuneiform resection. He had also done the operation with good results after various tenotomies had been performed and apparatus worn to no purpose.

**A Contribution to the Surgery of the Œsophagus.**—This was the title of a paper read by Dr. A. G. GERSTER. (See page 141.)

Dr. STIMSON thought that, even if feeding was carried on through a tube, regurgitation was possible, with the result of sepsis of the trachea. In a case under his observation, in which a tooth-brush was removed, the wound had been closed and the patient fed by a catheter, perhaps too heartily. At any rate, after the third day the food had shown itself in the wound.

Dr. MCBURNEY was surprised to note how little the practice obtained, after operations of the class under consideration, of employing rectal alimentation exclusively for a period. He had found it altogether the best thing to do. The wounds did better, the stomach had complete rest, and there was really no difficulty in securing to the patient ample nourishment for from three to five days. The introduction of the catheter was not without objections, while its withdrawal favored the introduction of deleterious matters into the wound in the neck. He thought the method of sewing up the œsophageal wound and packing the external one covered the ground, provided the œsophagus was left at rest, and the patient nourished for several days by the rectum.

Dr. F. LANGE suggested the method recommended by Langenbeck as worthy of trial in cases where the foreign body was of a certain shape and was located in certain positions. He had lately been successful in dislodging a whistle, of the diameter of a twenty five-cent piece, from a child's throat by this plan. By pressure against the lower circumference of the body it was dislodged and withdrawn through the mouth. He did not think that the act of swallowing could be excluded in these patients; mucus would always accumulate, and it seemed hard to debar them so long from fluids. Of course, a great deal depended upon the extent to which the œsophagus had been exposed to contamination during the operation. If septic trouble was apprehended, special care must be taken to guard against it.

Dr. GERSTER said he had stated in his paper that leakage was frequently observed during the first few days after sutures had been applied. In spite of this, union took place unless septic complications arose. Healing was hastened by the mechanical approximation of the edges of the wound, even if primary union did not take place. He believed the success of the suture depended upon the condition of the parts.

**Appendicitis.**—Dr. STIMSON showed an appendix vermiformis that he had recently removed. The patient had come to the hospital a week ago and had given a history of previous attacks of appendicitis. On operation, the appendix was found lying behind the cæcum, and closely adherent to it without a mesentery. Microscopical examination had demonstrated that the mucosa was lost and replaced by fibrous tissue and small, round cells. The follicles of Lieberkühn were also destroyed.

Ten cases of acute appendicitis had come under the speaker's notice lately. All of these had been treated expectantly, some of them by himself. In three suppuration had occurred. Two of the patients had died. Operation had apparently saved the third. He thought the facts worth consideration when the propriety of early operation was under discussion.

Dr. LANGE thought that statistics were very deceiving, and from such a small number of cases it was impossible to draw conclusions. The number of such cases, in order to decide whether early operation or the expectant plan should be the rule, was too small. He was inclined at times to agree to the expectant plan, and did not see the use of operating on an abscess through the free peritonæum at an early stage, which he thought was hardly likely to cause mischief. He thought that if at the end of the first week an operation was done, pus would most probably be found in contact with the anterior abdominal wall or could be reached through the rectum or by a lumbar incision. It would then be found unnecessary in by far the majority of cases to do a serious operation. The question was, any way, not yet solved, but by temporizing treatment in a large number of cases nothing was likely to be lost. There was a minority, however, in which operation could not come too early, and to distinguish those was a trial more worthy of surgical science than indiscriminate laparotomy, which for some time past had promised to become the fashion of the day.

Dr. STIMSON said he had not offered his cases as general, but as individual statistics. The two fatal cases had been treated expectantly by others and then sent to him for operation after general peritonitis had developed.

Dr. PARKER SYMS thought that some sort of ability to classify these appendicitis cases was essential before formulating rules as to operating. In cases which required operative interference at all the early operation was the proper one. In cases that had gone on to suppuration and in those that were dealt with by simple incision, extraperitoneally, the patients were not necessarily in a safe condition. He did not think the patient who had gone on to extraperitoneal abscess and had escaped the early

dangers was by any means in a safe condition. If we could ascertain by symptoms what cases were going to call for operation, the early one would be the one to choose.

Dr. F. KAMMERER thought that cases in which circumscribed suppuration had taken place about the appendix, which afterward led to general peritonitis, did not argue for early operation; when suppuration had started in the peritoneal cavity, on whatever day, we ought to interfere surgically. To diagnose this condition in its incipiency was of greatest importance. Then we should not meet with cases of general peritonitis from primary circumscribed abscess.

Dr. F. W. MURRAY cited a case in which he had just operated. The patient had had two attacks previous to the operation—his first attack seventeen and his second fifteen years ago. This case simply illustrated that under the expectant plan of treatment one could never be sure that the patient was permanently cured, a fact which decidedly lessened the value of the statistics quoted by advocates of this form of treatment.

Dr. R. F. WEIR did not think enough was known as yet on this subject to warrant the formulation of a hard and fast rule which could be adapted to the doubtful cases. The natural history of the catarrhal form was yet incomplete. He was yet unwilling to believe that this variety had such danger connected with it as the perforative and gangrenous forms. Each case in its acute stage required so far a special judgment. The question of an operation hinged, then, largely upon the presence of the signs of advancing peritonitis.

**Gangrene of the Testicle.**—Dr. GERSTER reported the following case: George O., a butcher, aged thirty-nine, was admitted on February 2, 1880, into the German Hospital, with an enormous emphysematous swelling of the left testicle. The organ had nearly the size of a man's head, was dusky, red, and hot, showed crepitus, and gave a tympanitic percussion sound. The patient, a powerfully built man, showed symptoms of most acute septic intoxication. He stated, on being shaken out of his stupor, that the swelling had come on three days before, suddenly, with much pain, after an exploratory puncture. Immediate ablation of the organ was done. The skin was preserved, and a very large wound cavity was filled with a packing of carbolized gauze. An almost immediate improvement of the patient's general condition had followed. The wound had healed rather rapidly by granulation. On February 26th the patient was discharged, cured.

The speaker also showed a specimen of a testicle, recently removed, with the following history: Abraham G., aged twenty-eight years, married, a peddler, was admitted into Mt. Sinai Hospital on November 11, 1891. He had had a chancre about three years before, and five months later a gonorrhœa. Had never noticed any evidence of secondary syphilis. Shortly after his attack of gonorrhœa he noticed that the right testicle was beginning to swell, but was not painful, and there was no fever. This swelling had increased slowly until it had attained nearly the size of his fist, when it remained stationary, and had been so for about a year.

His present illness had begun five days before. On returning home from his day's work, he began to have pain along the right spermatic cord, and the next day it was so bad that he went to a dispensary, where the doctor aspirated the tumor three times, drawing off a bloody fluid, but did not inject anything into the scrotum. That evening the pain became very severe and the testicle increased to nearly twice its size; he also had a chill, fever, and headache, and felt generally weak. He had had a chill every day since, and fever. The pain had been very severe, so that he had been unable to sleep. There had been no trouble in urination. The bowels were regular. The patient had vomited once. On his admission, his pulse was 100,

his respiration 26, and his temperature 103.4°. His general condition was good. His tongue was a little coated. The scrotum was of about the size of a large coconut. There was no impulse on coughing. The scrotal wall was tense, inflamed, and quite tender on pressure. There was slight tympanites. The left testicle, of normal size, was felt posteriorly and freely movable.

The operation consisted in ablation of the gangrenous testicle, the parenchyma of which was found converted into a brittle, semi-liquid pulp of a brownish-red color, containing abundant bubbles of gas. The tunica albuginea was throughout very much thickened, of a dirty greenish-yellow, and evidently necrosed. The necrosis was apparently extending here and there into the scrotal tissues, which were oedematous and also contained gas around the necrosed areas.

In four hours after the operation the temperature was 99° and he was feeling better. (*Note, January 29, 1892.*—The patient made a rapid recovery.)

Dr. WEIR had seen several cases in which the introduction of a fowl aspirator needle had been followed by necrotic processes. Two instances followed puncture for serous pleuritic effusion, and in two other cases the testicle became gangrenous from a similarly badly conducted exploratory puncture. He had also seen gangrene of the testicle from other causes.

Dr. F. LANGE had operated in one case where previous surgery had not led to infection. There was some constitutional disturbance and subacute fever. This condition had lasted for some time. The speaker had seen the patient in the second week. At that time the organ was considerably enlarged. On removal, it was found to be necrosed. There was no pus formation, there were no symptoms of decomposition, but there was considerable bloody infiltration. Embolism of a nutrient artery, most probably of a spermatic artery, seemed to have caused the trouble.

Dr. GERSTER added the history of another case of spontaneous gangrene of the testicle in a young man who, about nine months after castration, was readmitted into the German Hospital with an evident renal tumor to which he succumbed. Post-mortem examination revealed an enormous renal sarcoma involving more or less of the adjoining tissues, of course also the radical portion of the spermatic artery. There was no evidence of sarcoma about the scrotal cicatrix, but the assumption was very plausible, in view of the sudden, apparently embolic character of the gangrene, that a sarcomatous plug might have been carried into the terminal part of the spermatic artery, thus causing acute gangrene. The speaker referred to an excellent paper on the subject of spontaneous gangrene of the testicle by the late Professor Volkmann, of Halle.

#### NEW YORK NEUROLOGICAL SOCIETY.

*Meeting of January 5, 1892.*

The President, Dr. LANDON CARTER GRAY, in the Chair.

**Thomsen's Disease.**—Dr. C. L. DANA exhibited a male patient, thirty-three years of age, who presented the typical phenomena of this disease. The family and personal history of the patient were good. There was no specific trouble and had been no previous nervous disturbances. The first symptom noticed had been a weakness of the muscles, which had come on at the age of seventeen. Three years subsequently it had been found that, when the fists were closed, they could not be opened again voluntarily for some little time. These conditions had increased until at the present time the only muscles not involved in the process were those of the thighs and upper arms. The myotonia was most marked in the muscles of the forearms and legs. No

contractions of the pillars of the fauces were observed. There were no sensory disturbances. Reflexes were nearly abolished and could only be obtained by re-enforcement. There was slight increase of reaction to the galvanic current, but not to the faradaic. The author felt convinced, from very careful tests of the muscles, that the phenomena were confined to the muscles themselves, and that it was not due to a reflex influence, but that the disease was a purely muscular one.

**Peripheral Neuritis, or Possible Lesion of the Posterior Nerve Roots.**—Dr. W. M. LESZYNSKY presented a patient with the following history: A woman, fifty-three years of age, while trying to raise a heavy weight had injured the shoulder joint. Neuritis of the brachial plexus had developed within a few days. When she had first come under treatment, nearly six months after the accident, she had been suffering from extreme pain and tenderness in the course of the median and musculo-cutaneous nerves. There had been no circumscribed paralysis, but a general weakness of the entire limb. The pain had been relieved by treatment. Within two weeks the entire extremity had gradually reached a condition of complete anesthesia, including loss of muscular sense. Subsequently the adductor pollicis and the flexor longus pollicis had become paralyzed. This paralysis had disappeared, however, within ten days, and simultaneously there had been a restoration of all forms of sensibility, including the muscular sense, over the thenar group of muscles and the entire thumb, the rest of the limb remaining anæsthetic. There had been diminished faradaic irritability in the thenar, hypothenar, and interossei muscles. Any hysterical element could be excluded. He thought the diagnosis rested between a peripheral neuritis affecting the sensory nerve branches and a possible lesion of the posterior nerve roots.

Dr. MARY PUTNAM JACOBI did not see why Dr. Leszynsky was so positive in excluding hysteria as the probable cause of the condition in his case. The distribution of the anæsthesia was such as one might expect in an hysterical patient. The fact that there had been no other exhibition of any recognized symptoms of hysteria did not exclude the disease in such a case as just presented.

**Spasmodic Screaming.**—Dr. J. A. BOORN presented a patient, aged seventy-three, a peddler by occupation, who had been under observation in the Nervous Department of the Manhattan Eye and Ear Hospital for the past four years. He had also been a frequent visitor to the various clinics in the city. The patient had enjoyed good health up to nine years ago; about that time, after a week of great headache, he had had an attack of left hemiplegia with disturbance of speech. He had been ill in bed fourteen weeks, and during this time had suffered intense and constant pain in the head. The paralysis had gradually improved; the disturbances of speech had disappeared and he had returned to his business of peddling one year after the attack. Ever since the onset of illness he had had more or less head pain, localized over the right parietal region, and this he described as appearing in a spasmodic manner, shooting up to that portion of the head. The attack had been ushered in by a flexion of the ring and middle fingers of the right hand, the other fingers being straight; the whole hand had then been rapidly rotated, the attack culminating in a loud scream and the placing of the hand on the right side of the head. He had also complained of not being able to sleep, and his wife had corroborated this statement by adding that he was a nuisance to her and the neighbors by these attacks of screaming at night. These paroxysms could also be brought on apparently by suggestion, although the speaker had never been able to get the patient under the hypnotic influence. After going over the case carefully the speaker was inclined to believe that at the present time the patient was more of a simulator than anything else.

**Debate on the Therapeutic Value of Hypnotism.**—The CHAIRMAN said that his object in calling for such a discussion was to ascertain the opinions of New York neurologists in regard to the value of hypnotism therapeutically. He did not want to hear any historical data on the subject, but the personal experience of those who had given the matter serious attention.

Dr. DANA referred briefly to the work of the late Dr. Beard as being the only contributions made by an American author on this subject. From a long series of experiments that writer had been convinced that hypnotism was a real condition and not a myth. He had not been able, however, to produce complete hypnosis, although he had attached some value to suggestive therapeutics. The speaker had been able to produce complete hypnosis in fifteen per cent. of the cases submitted for experiment and only a partial state in from thirty to fifty per cent. As to its value as a remedy in any of the known neuroses, it was doubtful if it had any efficacy. There were many therapeutic measures which were so much easier of application and which possessed recognized virtues, that it seemed to the speaker unwise to exchange them for something with such subtle power and so difficult of control as was hypnotism. Taken altogether, it was a remedy that could rarely, if ever, be used with benefit.

Dr. G. W. JACOBY said that he had been through two epidemics of hypnotism, the first lasting from 1880 to 1884, and the second in 1888. In order to indicate just what position he occupied in regard to the value of hypnotism as a therapeutic remedy, it was necessary for him to review his work in this direction. In old note-books he had found a record of nine cases marked "cured" in which hypnotism had been the remedy. On following out the further histories of these cases, which had been of various forms of hysterical neuroses, it had been found that in every instance there had been relapse of the trouble. This result had been the cause of the speaker's abandoning hypnotism as a therapeutic agent. While it might possibly be good for some subjects, for the control of some symptoms temporarily, why should we use a method that was laborious and surrounded by mysticism and charlatanism, when other remedies had to be resorted to ultimately anyway? The only way in which any conclusion could be arrived at in regard to the therapeutic value of hypnotism was by means of statistics, and these so far had been more or less unreliable.

Dr. WALTER VOGHT described the method of producing hypnosis employed at the Vanderbilt Clinic. Some bright object was held before the patients' eyes, and at that they were told to gaze while the physician encouraged them to try and sleep. Such means had rarely failed to produce the desired hypnotic condition. In no instance had had effects been observed to follow its use; in some a slight pallor had come on, but nothing of further consequence. The therapeutic application of hypnotism was successful in most of the cases—such as neuralgias and persistent pain. The speaker thought that it was to be recommended in this class of cases.

Dr. E. D. FISHER said that, so far as his experience and personal observation went, he did not favor the use of hypnotism as a therapeutic remedy. He had not as yet seen or heard of any permanent successful issue from such procedure. He thought that it might also be a dangerous measure in many cases, especially in certain mental conditions. At any rate, if hypnotism was to be used at all, it should be only with the greatest precaution.

Dr. J. W. COLLINS had used hypnotism in thirteen cases, and was able to report a cure in five of these. It was not his practice to use the remedy promiscuously, but when he had decided that the case was suitable for hypnotism he had carried out the system of mental suggestion, and had been able to get good results

from it. While he did not maintain that hypnotism was a remedy for all nervous diseases, he was satisfied that it possessed therapeutic value in certain cases. He thought that it was a great mistake to say that patients were non-hypnotizable if they did not succumb to the influence in a short time. He had seen the masters in this branch at work at patients one and two, and even three, hours in some instances before they could be brought under the hypnotic influence. He did not want to appear as an enthusiastic advocate for hypnotism, but he was convinced that it had a field in certain psychical conditions, and especially in moral perversions. Considering the fact that the present method of dealing with these cases offered but little in the way of cure, there should be no hesitancy in at least giving hypnotism a fair trial, and not being satisfied with simply an attempt or two, but persisting until such a condition of the patients was brought about, so that mental suggestion could be responded to. If carried out consistently, the speaker was sure that hypnotism would offer more as a moral educator than any other measure that had ever been advanced.

Dr. LESZYNSKY thought that the length of time that it took to get the patient under the hypnotic influence was a matter of indifference. As yet there were no statistics to show the bad influence of hypnotism, but in cases where he had failed to produce hypnosis the patients had been left in an uneasy, uncomfortable state. He did not think hypnotism by any means devoid of danger. He reported the case of a child twelve years of age whom he had treated for hysterical attacks of laughing and crying. She had improved very much under ordinary attention, and had finally passed out of his hands. Some time subsequently there had been a slight return of the trouble, and the mother had taken the child to some one who had tried hypnotism, the first attempt being unsuccessful; but it had been persisted in until complete hypnosis had been brought about three or four times. From this time on all of the symptoms had become exaggerated, and when the author had seen the patient again she had developed all of the phenomena of hysteria. He felt satisfied that hypnotism was responsible for the deterioration in the nervous tone and the development of hysterogenic zones. It had been two years since he had practiced hypnotism. The last patient upon whom he had tried it had been suffering from singultus; during the hypnotic state the spasm had been abolished. Suggestion at this time that the paroxysm would not return when consciousness was restored had proved a failure, as the spasm had returned in an aggravated form. As for hypnotism being applicable in insanity, it was thought rather doubtful that it could be done at all, for the reason that the degree of concentration necessary could not be obtained in this class of patients.

Dr. BOOTH had during the past four years made use of hypnotism in twenty-four cases—fifteen in females and nine in males. Of the fifteen females, ten had been hypnotized easily and had responded to suggestion; in five no hypnotic effects had been produced, although repeated attempts had been made. Of the nine cases in males, six had been failures. The histories and treatment of four cases were then read in detail. Case I.—A young girl, aged seventeen years, suffering with tremor of the left upper extremity, had been hypnotized daily for a week, during which *séances* proper suggestion had been made. At the end of that time the tremor had entirely disappeared and had not returned a year after treatment. Case II.—Hysteroid attacks in a girl aged nineteen years. She had been easily hypnotized, and had been markedly lethargic, going into a deep sleep from which it had been difficult to arouse her either by suggestion or strong measures. Subsequent *séances* had not produced such marked effects, and had been successful in lessening the number of attacks. One attack only had occurred during the past year. Case

III.—Double ptosis. The patient had been easily hypnotized, and after fourteen *séances* there had been marked improvement. Case IV was another patient with hysteroid attacks, which had been ultimately cured by hypnotism.

Dr. B. SACUS had not been able to do much with hypnotism, and as yet had accomplished nothing therapeutically. He had tried the method in cases of hystero-epilepsy and where persistent pain had existed for years; in every instance the therapeutic effect had been absolutely *nil*. The only two cases in which a certain amount of benefit had seemed to be derived from hypnotism had been of nerve-deafness occurring in two young women. The improvement had continued during four weeks in one case, and three months in the other. He thought, however, that hypnotism, so far as any real therapeutic value was concerned, was only a fashion at present, and that it would soon be laid on the shelf.

Dr. JACOBI described a case which had recently come under her observation, the course of which possibly bore some analogy to the way in which hypnotism operated upon the nutritive states through some controlling mental emotion. The patient, a woman of emotional characteristics, had complained of severe pain in the shoulder joint. There had been present much swelling and anæsthesia. Despite all treatment, the condition had increased in severity. After the tenth day hysterical attacks of screaming had come on, followed, fourteen days after the onset of the trouble, by considerable vomiting of blood. About this time the patient's child had become dangerously ill and had died in a few days. From this time on all her symptoms connected with the shoulder and the general condition had gradually subsided and had finally disappeared. Health in a short time had been completely restored. The speaker thought that this was a clear case of great mental emotion having the power of reorganizing and controlling the nutritive states, as shown in the rapid recovery when the mind was concentrated on the illness and death of the child.

The CHAIRMAN had practiced hypnotism since 1886 in hundreds of cases in his hospital wards, but had finally given it up in this class of patients, as he had found that it had a demoralizing influence, and that moral control over them was lost by persisting in its use. In some cases where he had tried hypnotism he had found that his patients would leave him and go to some one else. He thought, however, that in the present study of hypnotism we were only on the verge of a great developmental knowledge of psychical laws which might prove to be of great value. From his experience in the use of this agent as a therapeutic measure he was not able to say in what class of cases or individual case it would or would not be beneficial. If he could draw any deduction, he would say that the hysterical cases offered the best results. No one understood the nature of hysteria, and there were no conclusive criteria by which hysteria could be diagnosticated; but in the symptoms laid down as such, hypnotism had produced some amelioration, although relapses occurred. In functional symptoms, such as delusions of fear, fright, timidity, and so forth, good results were obtained by hypnosis. In other neuroses, such as neuralgias and organic diseases of the nervous system, the benefits were not so good as from other known remedies. The speaker had never been able to hypnotize an insane patient, and the practice had filled paranoiacs full of delusions. Altogether, no good results were obtained in these two classes of patients, but much harm in the latter. There need be no difficulty in hypnotizing patients; if it could not be done in one way it could be done in another. The author had found that, where patients were hard to get under the influence, they were apt to sink into coma afterward. He had had such a case, where the patient, when observed for a short time after being hypnotized, had been al-

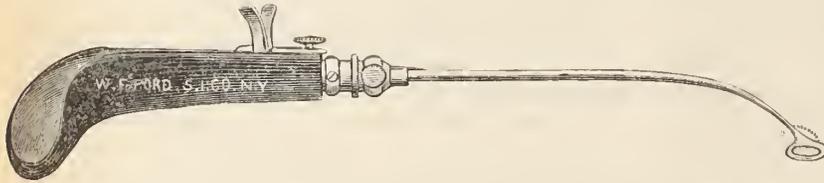

most in a comatose state, and had been very ill for the remainder of the day. He had never heard of a death being produced by hypnotism, but did not think it unlikely that it might happen. He would not, however, condemn hypnotism until it had had a further and more conscientious trial.

## New Inventions, etc.

### AN INSTRUMENT FOR THE REMOVAL OF HYPERTROPHIED TISSUE FROM THE BASE OF THE TONGUE.

By WALLIS F. CHAPPELL, M. D., M. R. C. S.

THE increased glandular tissue so often found at the base of the tongue is usually treated by the cautery, caustics, and astringents. These methods are not so satisfactory as we could wish, on account of the frequent applications necessary and the unpleasantness to the patient from the tardy healing of the cauterized surface. The instrument shown in the accompanying cut is intended to take the place of the cautery in most cases. It should not be used where there is a collection of vascular nodules accompanied by a varicose condition of the vessels at the base of the tongue, but on the large pale masses which so often completely surround the epiglottis. It is not necessary to remove

every particle of this tissue, but simply to pare off sufficient to relieve the symptoms. Before using the instrument the throat should be sprayed with a one-per-cent. solution of cocaine and then, either by the guidance of a laryngeal mirror or after pulling the tongue forward, the instrument is placed in position and the necessary amount of tissue removed. The hæmorrhage is slight and the cut surface heals rapidly. This instrument will also remove the uvula more satisfactorily than anything I know of, and, with a little experience in using it, is invaluable for the removal of adenoid or granular tissue from the posterior wall of the pharynx.

## Miscellany.

### The Nervous and Mental Phenomena and Sequelæ of Influenza.

—At a meeting of the Philadelphia County Medical Society held on January 13th, Dr. Charles K. Mills read the following paper:

All practitioners have been struck by the prominence of nervous and mental phenomena in influenza; and much has been written, but mainly in a desultory way, about the symptoms of the disease which are referable to the nervous system, and its more or less persistent nervous and mental sequelæ. The part played by the nervous system in the ætiology and history of the disease has been variously interpreted. One holds that it is a "nervous disease," without explanation; another describes it as a pneumogastric neurosis; another as a neuropathy due to ptomaine poison. According to Bloec, cited by Church,\* the primary infectious action takes place upon the nervous system during the disorder, while sequelæ are to be attributed to secondary infection from ptomaines. Cheston Morris,† of Philadelphia, advances the

theory that the general symptoms of influenza may be traced to a derangement of function, or partial paralysis of the pneumogastric nerve, and that the affection is brought about by conditions of the atmosphere which particularly tax the cardio-pulmonary apparatus which is regulated by this nerve, a view which, after all, relegates the disease to an atmospheric or infectious cause. Graves long ago referred the bronchial and pulmonary symptoms of grippe to lesions of the nervous power of the lungs, and Blakiston regarded it as a disorder of the nervous system, with concomitant derangement of the organs of digestion, circulation, etc. Levick,\* who cites the last two authorities, holds that certain symptoms are produced when the poison is expended on the sensorium, and certain others when its influence is chiefly exerted on the respiratory centers.

The analogies or relationships between influenza and other diseases generally recognized as belonging to the nervous system, either primarily or because of the situation of their most notable lesions, have been strongly brought out by able writers, as by Levick, for example, who has even suggested that epidemic cerebro-spinal fever, or cerebro-spinal meningitis, may be simply a malignant form of influenza, a view to which he was led because of the resemblance in the symptoms of the two diseases, which differ in degree rather than in nature, and also because for three centuries the two have occurred coincidently or in close sequence.

Grasset and Rauzier,‡ in a monograph on the grippe of 1889-'90, lay great stress on the enormous predominance of the nervous over the catarrhal elements in the epidemic, as evidenced in the high fever, great cephalalgia, the marked delirium, the widespread pain, and the excessive nervous irritability. They refer to cases communicated by M. Coustan, in which the entire symptomatology of the disease seems to have reduced itself to a horrible migraine. They review the literature, which shows that writers of various countries are unanimous in proclaiming the importance of the nerv-

ous element—referring to Austrian, Russian, Belgian, German, English, and Polish contributions.

According to Schmitz,‡ who read a paper on the subject before the Psychiatric Society at Bonn, influenza is a disease of the nervous system with secondary involvement of the heart, lungs, and digestive organs. In several hundred cases which he observed the nervous symptoms were always primary, followed in every case by secondary involvement of the other organs.

What seems to be needed is an analysis and practical grouping of the facts, almost too numerous to handle, which show the important part played by the nervous system in the development, progress, and results of the disease. How is the nervous system affected by influenza? What are its primary or direct effects on the nervous system, and what are some of the more persistent and permanent impairments, and how are these determined by the disease? What are its acute nervous and mental phenomena, and what are the most common sequences? What is the probable pathology of these states, and what treatment is best in view of the neurotic characteristics of the affection?

The briefest consideration of the subject brings forcibly to mind the fact that all diseases of infectious or toxic origin—epidemic, endemic, sporadic, or accidental—may strike any or all parts of the nervous system with a result which will be proportionate, first, to the virulence of the infecting agent; and, second, to the resistance of the individual, whether this is due to constitutional predisposition or to reductions, the result of previous injury or disease. The microbes may differ, but a bond of union and close resemblance can be recog-

nized between the effects on the nervous system of all contagious and infectious diseases, as variola, scarlatina, diphtheria, measles, whooping-cough, typhoid or typhus fever, leprosy, mumps, cholera, erysipelas, puerperal fever, influenza, or cerebro-spinal meningitis; of all of such constitutional and diathetic affections as tuberculosis, gout, rheumatism, and diabetes; and of all such toxic agents artificially introduced into the system as alcohol, mercury, lead, arsenic, copper, and poisonous gases. These diseases, these diatheses, and these poisonous metals and gases produce, or may produce, nervous and mental phenomena of the same character, differing in degree in particular cases and for special reasons.

In all these affections at the time of acute onset, if the illness is of a serious character, such symptoms are present as great mental and nervous debility, irritability, restlessness, sleeplessness, or the opposite states of torpor, stupor, hebetude, or coma; delirium; vertigo or syncope; headache, browache, napeache, backache, and limbache; pains of all degrees of severity referred to various nerve areas; hyperæsthesia of the skin, of muscle-masses, or confined to nerve-trunks or branches; spasms, local or general, and with or without unconsciousness; sometimes mental disturbance amounting to a true mania or melancholia. During the progress of such affections any one or several of these enumerated symptoms may be present. Supra-orbital pain, for example, may be the only prominent nervous symptom in a case of influenza; headache and backache in diphtheria; hyperæsthesia in mumps, diabetes, or gout; and mania in a case of puerperal infection. Any infectious or toxic disease may, in brief, produce the same symptom, syndrome, or train of phenomena; and—which is the main point—for the same reason, namely, because of the introduction into the system of an agent which directly and powerfully poisons nerve centers, and possibly also nervous conducting tissues.

Following all infectious, diathetic, or toxic diseases, moreover, or directly springing from them, common experience teaches that we may have great nervous or general weakness; forms of insanity of the depressive type; paresis and paralysis of every grade from an affection of a single muscle to that of all the extremities, and even more; localized spasm or cramp; general convulsions; pains in nerves, muscles, and joints; and losses or perversions of sensation.

These symptoms and conditions, which may occur at the onset, during, or after the subsidence of any infectious or toxic disease, are those which constitute the nervous features of the prevailing epidemic. I have introduced the subject in this way because it seems to me that it is this comprehensive grouping of generically similar phenomena which enables us to most readily grasp a subject even for practical purposes. We differentiate phenomena in our daily labor, which we can only understand by properly grouping them, and by referring them to a common or to related causes.

Any attempt to classify the nervous and mental phenomena of influenza must be attended with great difficulties. These are, in the first place, symptoms and conditions which, although manifested in non-nervous organs, are directly traceable to a nervous origin; secondly, affections which would be recognized by all as properly referred to the nervous system; and, thirdly, affections occurring in nervous tissues and organs, although, strictly speaking, not nervous diseases.

I will refer very briefly to the first of these classes, although of much importance. I will not, however, discuss the nervous origin of the fever of influenza, nor will I attempt to explain the catarrh, indigestion, etc., on some neurotic theory, as such a method might lead us anywhere, and for our present purposes would be unprofitable. I wish simply to emphasize the fact that some of the most prominent pulmonary, cardiac, and vascular affections of influenza can best be explained on neural theories. Many personal observations have led me to the conclusion, not new, which has recently been well presented by Elliott,\* of New Orleans, that the pneumonias of influenza are often due to vaso-motor paralysis, that they are, in fact, forms of blood stasis or passive congestion from vaso-motor paralysis, which in its turn is dependent upon the action of the infection upon the pneumogastric centers and the nervous system in general. A distinct difference can be made out between the true pneumonic lung and this "grip-lung," as it has been

termed by Elliott. Graves long ago attributed the œdema of the lungs which occurs in influenza to an affection of the vagus.

"The grip-lung," according to Elliott, "has a long and very varying condition of passive blood stasis unaccompanied by râles. If resolution occurs within three or four days, it is accompanied by large mucous râles, and no time is given for the slow appearance of bronchial breathing or bronchophony; but during the long continuance of the blood stasis an exudation occurs, increasing slowly, which will give, in time, some bronchophony and bronchial breathing, but never so complete as in pneumonia. Resolution never occurs in these cases with the suddenness that characterizes it in acute pneumonia. The condition passes off as gradually as it formed. The sharp, clear-cut, and sudden phases of the pneumonic attack separate it clearly from the obscure, irregular, and slow phases of the *grip-lung*."

Many disorders in various parts of the body are best explained on this theory of local vaso-motor paralysis, although it is not necessary to attempt to force this explanation for all. Hæmorrhages, minute, or even of considerable size, occurring in diverse localities, as in the retina, membrana tympani, and internal auditory apparatus, or in the skin, or mucous or serous membranes anywhere, may be due to deficient vaso-motor tonus. Brain, kidneys, liver, or pelvic organs may suffer from forms of passive hyperæmia, subacute or chronic, which are in fact due to forms of vaso-motor palsy. Occasionally we meet with cases of vaso-motor disorders of the extremities, such as flushed or pallid fingers.

Even trophic affections have occasionally been observed. Wilson,\* for example, refers to gangrene of the lungs as one of the less common complications. Abscesses of the limbs have been recorded. Grasset records two observations of eschars occurring in young subjects in the absence of prolonged decubitus. The greater tendency in surgical cases to suppuration may have its best explanation in the depression of healthful vaso-motor and trophic influence.

The peculiar forms of pulse, and the uncertain or perverted action of the heart, extending in some cases to cardiac palsy and death, are in a strict sense nervous phenomena due to paralysis, partial or complete, of the inhibitory apparatus of the heart.

Let me take up those symptoms and affections which would clearly be recognized as belonging to the nervous system.

I believe, with Church, "that the infection of influenza has a marked action upon the nervous system which may give rise to immediate acute manifestations or to remote and persistent conditions; and that in the predisposed, grippe is competent to cause marked excitement or great depression of the motor, sensory, and mental nervous apparatus."

Great nervous and mental prostration, both as an acute manifestation and as a persisting sequel, has engaged the attention and required the treatment of all practitioners. The mental depression often present as an initial symptom has been in some cases simply overpowering. Some of the patients are affected like individuals whose mental and motor centers have been poisoned to the limits of human endurance, while still permitting the retention of consciousness. In other cases even consciousness itself has been overwhelmed.

Not a few patients who suffered from attacks of influenza during the early period of the present epidemic are still victims of profound neurasthenia. I refer now to cases which are not distinctively of the melancholic type. These neurasthenics are unable to endure a fair amount of work; their nervous forces are soon routed; they are weak, worrisome, and unrecuperative. The cardiac weakness which has been left is undoubtedly in part the cause of this neurasthenia, and with reference to this Church says that "the persisting neurasthenic condition which so usually follows influenza is attributed by some to cardiac weakness of nervous origin, and this contention is not without weight, if it is observed that, even after appetite, sleep, body-weight, and physical functions have long been restored, the slightest exertion immediately produces disproportionate fatigue, accompanied almost invariably by either a retarded or more frequently accelerated pulse, and rarely by præcordial distress and even by angina pectoris."

Curtin and Watson,† whose experience in influenza has been con-

\* Elliott. *Climatologist*, i, 1, August, 1891.

\* Wilson. *American System of Practical Medicine*, vol. i, p. 870.

† Curtin and Watson. *Climatologist*.

mous, say that, although general nervous prostration often extended over long periods without any discoverable local cause, it was always worth while to examine the urine with care. "Sometimes a nephritis, sometimes a faulty digestion or hepatic inaction, seemed to underlie the general condition in latent form. These cases, by enforced rest and attention to local complications, gradually recovered. These cases, and nervous cases generally, were very disappointing when sent to the seashore during convalescence."

Among organic nervous diseases which have developed during the influenza or have been left in its wake are in the order of their frequency, so far as my personal observation has gone, neuritis, meningitis, myelitis, and cerebritis, or various combinations of these inflammatory affections—as, for example, concurrent neuritis and myelitis, meningo-myelitis, or meningo-encephalitis.

Probably no single affection of the nervous system has been so common during and after the grippe, and particularly as a sequel of the disorder, as neuritis. Almost every variety of neuritis as regards location and diffusion have been recorded, and have come under my personal notice. Multiple neuritis, while not common, has not been rare; and I have seen a concurrence of this affection with poliomyelitis in the same case. Isolated neuritis of almost every cranial nerve has been recorded, with such resulting conditions as optic atrophy, loss of smell and of taste, ophthalmoplegias, both internal and external; oculomotor, facial, and bulbar, or pseudo-bulbar palsies of various types, including true pneumogastric paralysis. Several cases of specially located affections of the sympathetic ganglia or nerves have been recorded. Of the forms of local neuritis most common might be mentioned the supra-orbital, intercostal, sciatic, and plantar.

An interesting case of neuritis with a myxœdemoid condition of the limbs presented herself at the Philadelphia Polyclinic recently. She had a sharp attack of influenza five weeks ago, having been in good health up to that time, except five years since, when she suffered for several weeks with inflammatory rheumatism. On recovering from the influenza, the attack not having been especially marked with nervous symptoms, she was extremely weak in the legs, and was scarcely able to drag herself around. In a few days her feet and legs began to swell and to be painful, and soon became of enormous size and exquisitely tender. She has gradually improved, but still has a condition of firm swelling, which does not pit on pressure, from her knees to her ankles, and she also still has great tenderness on squeezing the feet or ankles, or in handling the nerves or muscles of the limbs. She has no cardiac affection.

The articular pain and other so-called rheumatic manifestations so numerous during and after attacks of the grippe are, after all, best explained on the theory of infectious neuritis or myositis.

These cases with articular and other pains, and with swelling, recall the endemic or epidemic form of multiple neuritis known as beri-beri, in which the chief phenomena are œdema and paralysis of the limbs, with marked pain, hyperæsthesia and paræsthesia, followed later by anæsthesia, lost knee-jerk, and depressed electrical reactions. Myositis certainly, and probably also periostitis, occur as complications or sequences of the influenza, and usually in association with neuritis of some type.

Many of the reports speak of the frequent occurrence of various neuralgias. Doubtless a distinction is seldom made by observers and recorders between neuralgia and neuritis, which are or may be separate affections. Practically these cases should be regarded as neuralgic, in which pain is referred to certain nerve lines or radiations, but in which pain on pressure, and the other phenomena of neuritis, such as anæsthesia, vaso-motor and trophic disorders, and even paralysis, are absent. In my own experience the cases which could properly be diagnosed as neuritis are by far the most common. The distinctively neuralgic pains are probably due to toxæmically depressed or exhausted sensory nerve-roots or centers in the cord and bulb.

Of diseases of the spinal cord proper, occurring as complications or consequences of influenza, the reported cases are not numerous, but they are none the less important. A few cases of myelitis have been put on record by native and foreign observers—one that I recall in which all four extremities were paralyzed. As would be expected, in accordance with the analogies with other infectious and toxic diseases,

anterior poliomyelitis is the most common type. I have had several cases of temporary paralysis of one or more limbs, which, owing to the absence of pain and of cerebral symptoms, were apparently spinal in their origin, and probably light forms of inflammation. Concurrent multiple neuritis and poliomyelitis has already been referred to as having been observed by me in one case, in which the neuritis, which was not severe, soon disappeared, but a limited paralysis, evidently spinal in character, was left behind.

Several observers have reported cases of bulbar paralysis, and one striking example of this disease, attributed to the grippe, has come under my own observation, although exactly how far the influenza was responsible it is difficult to say. This patient, a clergyman, had a severe attack of influenza in May, 1890, and during its progress continued to work, and ate but little. In a very short time he noticed he was losing power in his hands, which soon atrophied. In January, 1891, he began to have difficulties of speech, and, briefly stated, the case went on until November, 1891, when he was first seen by me; his symptoms were those of well-marked bulbar paralysis, with progressive muscular atrophy, chiefly involving the upper extremities.

In accordance with analogy, we would expect the occasional occurrence both of nuclear polio-encephalitis, and even rarely Strümpell's cortical polio-encephalitis. One or two of the few cases of probable polio-encephalitis of the latter type have occurred in patients suddenly stricken with fever, loss of appetite, and other symptoms which may have been due to infection.

Priester\* has reported the case of a man, fifty-four years old, who was taken with influenza in February, and in the beginning of March was seized with extremely violent headache which resisted all medication, and later the patient became deeply somnolent, remaining in this condition for four weeks; he could be aroused, but was apathetic and soon slept again. Reflexes and temperature were normal; pulse from 40 to 60. The patient had no paralytic symptoms, and slowly improved. His affection, according to the reports of the case, closely resembled Gerber's disease—paralyzing vertigo—although the latter is a disease of the warm weather. Tumor could be excluded by the absence of all focal symptoms a year before the attack. The most probable cause he believed was a pathological process, involving the central gray matter of the third ventricle, which would bring the disease into close relation with polio-encephalitis of the nuclear type. Dr. G. J. Kaumheimer, who translated this report for the *Review of Insanity and Nervous Disease*, December, 1891, observed an exactly parallel case which originated in April, and lasted into July before recovery took place.

That meningitis, either cerebral, spinal, or cerebro-spinal, occurs during the decline of the influenza can not be doubted in the light of the evidence which has been presented by various observers, and particularly during the epidemic of the last three years. It is, however, a comparatively rare concomitant or complication. Some of the facts adduced as proofs of the existence of meningitis, and some of the cases reported as examples of the disease, are clearly instances of improper interpretation. The intense cephalalgia and rhachialgia; the atrocious pains variously localized in the face, trunk, limb-nerves, muscles, or joints; the vigilant delirium, with hallucinations and delusions, sometimes assuming great gravity; the intense vertigo, with or without nausea and vomiting—these and other well-known nervous manifestations which are so prominent in many cases at the initiation of the disease are not necessarily evidences of meningitis, or even of meningeal hyperæmia. Rather they are due to an overwhelming toxæmia of the nerve centers and of the brain. Severe and terrible in character at first, they frequently pass away almost as rapidly as they came, which would not be the case if they were the evidences of a true meningitis. The enormous prostration which is left behind shows that the centers of nervous energy have been subjected to a depressing agency of great virulence, not that merely enveloping membranes composed mainly of fibrous tissue and blood-vessels have been congested or inflamed. No

\* Priester. *Wien. med. Woch.*, No. 27, 1159. In *American Review of Insanity and Nervous Disease*, December, 1891.

reason could be given why such congestion or inflammation should leave such results.

The reports of cases terminating fatally because of meningitis, and even the reports, personal or official, of the frequent occurrence of this affection, must be received cautiously, and sometimes incredulously. They are only to be relied on when confirmed by autopsies, or when from observers who are accustomed to closely differentiate the meaning of nervous symptoms, and particularly of pain.

It may also be worth while at this point to refer to the somewhat frequent diagnosis of chronic meningitis as one of the sequelæ of the disease. This diagnosis is usually made because of the presence of more or less persistent pain in or on the head. Experience has led me to believe that this pain is usually neuritic rather than meningeal. Even deep-seated intracranial pain does not necessarily indicate meningitis. It may be due to neuritis, just as certainly as a pain in the hand or foot. The fifth nerve has an immense distribution within as well as outside the cranium, largely to the dura mater but also to other tissues and parts. It is a pathological possibility to have dural neuritis without a pachymeningitis, and this is the true explanation of some pains, both acute and chronic, which are present in other diseases as well as in influenza.

The form of meningitis most likely to be present in influenza is inflammation of the pia-arachnoid or soft membranes, now often designated leptomeningitis. From observations, corroborated by autopsies, I know that this affection may exist without pain, while pain of varying degree of severity, and usually intense, is practically invariable in pachymeningitis. Leptomeningitis, however, is not usually without pain and hyperæsthesia as symptoms, but it may be absent, and its presence or absence will depend upon the location, extent, grade, and complications of the meningitis.

While believing that these criticisms upon the sometimes hasty and the too frequent diagnosis of meningitis in influenza, and indeed in many other infectious and febrile diseases, are just, and can be sustained, it remains true that a genuine meningitis, sometimes of malignant type, may appear during the progress or closely following influenza. Some very competent observers have reported cases of this character, and in a very few instances the diagnosis has been confirmed by autopsies. The diagnosis should be made to hinge upon the signs and symptoms which would be satisfying as to the occurrence of meningitis from any cause; not alone on the presence of such phenomena as headache, vertigo, and vomiting, but on such more convincing manifestations as optic neuritis, and localized spasms or palsies, either cortical or of cranial nerves.

The fact that meningitis, and even the cerebro-spinal form, does occasionally occur in influenza, is by no means proof that this disease and epidemic cerebro-spinal fever are identical. It simply emphasizes the point with which I started—namely, that every infectious or poisonous agent introduced into the economy may produce the same or similar pathological results in the nervous system. Largely according to the vulnerability, special or general, of certain tissues and organs, will be the preponderance of this or that form of so-called disease—for instance, of neuritis, myelitis, meningitis, cerebritis, or of combinations of these affections. All infectious and toxic diseases give neuritis as the most common acute or chronic inflammatory manifestation, although myelitis, cerebritis, and meningitis may occur. Even in cerebro-spinal fever, as I was perhaps the first to point out, multiple neuritis is a common complication; but the infection being virulent and overwhelming, we may not only have meningitis, but even meningo-encephalitis, or meningo-myelitis, with all their malignant phenomena and permanently disastrous results.

Vertigo is another symptom like pain, often improperly referred to meningeal or cerebral inflammation. It is sometimes due to such disease, but, occurring in influenza, it may arise from other causes, as, for instance, from extravasations into the labyrinth or other portions of the auditory apparatus.

Müller\* reports the case of a man, fifty years old, who after influ-

enza presented great physical exhaustion. In a few weeks his mind seemed affected and he became somnolent, so that he could be roused only with difficulty and would then fall asleep again. In this respect the case was much like the one reported by Priester. Pain upon pressure was present over the vertebrae, the neck was rigid, the pulse was small and irregular, the skin reflexes were diminished, and the tendon reflexes were absent. In two weeks he began to improve. The author believed the case was one of spinal cerebro-spinal meningitis, similar to that seen after infectious disease.

Without entering into a discussion of their pathology or their peculiarities, I will briefly mention a few other forms of nervous disorder occurring during or as apparent sequelæ of the influenza, examples of which have come under my personal observation. Convulsions have been reported by various observers, and in a few instances the convulsive habit has been established, and the patients have remained up to the time of report as cases of epilepsy. I have seen two such cases. Hystero-epilepsy and other grave hysterical phenomena have been initiated, or have recurred in cases in which the symptoms had long been dormant. Of local spasmodic affections I have seen no records, but one case of persistent tonic torticollis, with some pain and tenderness in the spinal accessory distribution, has been in attendance at the Philadelphia clinic. Two cases of facial paralysis, occurring immediately upon the heels of influenza, have come under observation.

Many affections not of, but occurring in, the nervous system have been reported as complications or sequences of the influenza. These include such affections as apoplexy, due either to hæmorrhage, thrombosis, or embolism. One of my Polyclinic patients, a man thirty-seven years old, was attacked with influenza in January, 1890. He was not confined to bed, but suffered severely from headache, cough, and persistent general weakness, and in February he was suddenly paralyzed in the right half of his body, and completely aphasic. Well-marked cardiac murmurs were present, and the grippe in this and similar cases is probably causative by lighting up old endocardial trouble, or through the blood dyscrasia and general prostration which it leaves.

Various observers have reported cases of monoplegia and hemiplegia, without indicating the pathological character.

Recently, in consultation, I saw a typical hæmorrhagic apoplexy occurring in a case of influenza in a woman, about sixty years old, who had previously been in fair health, and was not known to have had any disease of the kidneys or heart, although her vessels were somewhat atheromatous. Dr. S. S. Prentiss,\* of Washington, has reported three cases of cerebral apoplexy occurring during the progress of the influenza: one was a man of fifty-seven years of age; another in a man of eighty-seven; a third in a woman of sixty-seven. One of these was probably hæmorrhagic; the other two, from the histories, were probably from thrombosis. In cases of this character the infection of the disease acts to bring about an apoplexy both by the changes which it produces in the blood, by its effects upon cardiac action, and by the general debility induced. Such apoplexies might occur from other depressing causes; they are to be regarded not as phenomena, but rather as accidents of the epidemic.

Uræmic convulsions in patients suffering from chronic Bright's disease have been precipitated by the influenza, and it has seemed to me to have been active in lighting up lurking syphilitic diseases.

In one case of parietic dementia of somewhat irregular type, seen in consultation, the initial symptoms of the disorder were observed soon after recovery from a severe attack of grippe, the wife and friends of the patient, in fact, attributing the mental disorder to this attack. The probabilities are that syphilis was present, but latent, prior to the epidemic.

Purulent meningitis and brain abscesses have been somewhat frequently noted in connection with the numerous instances of purulent otitis media.

The relations of influenza to insanity have not received much attention from writers. Mairet,† of Montpellier, has recently published a

\* Prentiss. *Medical News*, August 29, 1891.

† Mairet. *Grippe et aliénation mentale*. Montpellier and Paris, 1890.

\* Müller. *Berlin. klin. Woch.*, No. 37, 1890. Cited in *American Journal of Insanity and Nervous Diseases*, December, 1891.

lecture on the subject delivered at his clinic for mental and nervous diseases. Rush, who is referred to by Mairet, speaking of the epidemic which lasted from 1789 to 1791, and particularly of the year 1790, mentions that several persons were stricken with symptoms of insanity, and that one attempted suicide; he also speaks of several having had hallucinations of sight. Bonnet, reporting on the epidemic of 1837, cites one case which was stricken with a furious mania as the result of the grippé; and Petrequin, referring also to the same epidemic, records several patients tormented by melancholy ideas, and states that four or five suicides were accomplished or attempted at the hospitals in Paris.

The following conclusions compress into small compass so much that is valuable with reference to the relation between influenza and the psychoses that I can not do better than quote them. They are reported as the conclusions arrived at by Dr. Leledy, and were presented to the Medical Society of London by Dr. Savage: \* 1. Influenza, like other febrile affections, may establish a psychopathy. 2. Insanity may develop at various periods of the attack. 3. Influenza may induce any form of insanity. 4. No specific symptoms are manifested. 5. The rôle of influenza in the causation of insanity is a variable one. 6. Influenza may be a predisposing or exciting cause. 7. In all cases there is some acquired or inherited predisposition. 8. The insanity is the result of altered brain nutrition, possibly toxic. 9. The onset of the insanity is often sudden, and bears no relation to the severity of the attack of influenza. 10. The curability depends on general rather than on special conditions. 11. The insane are less disposed to influenza than are the sane. 12. In rare instances influenza has cured psychoses. 13. The insane may have mental remission during the influenza. 14. There is no special indication in treatment. 15. Influenza may lead to crimes and to medico-legal issues.

I can indorse from experience almost every one of these conclusions. With reference to the statement that no specific symptoms are manifested, it should be said that while this in a general sense is true, the most frequent type is a form of melancholia.

The cases of active insanity have been observed at the onset of influenza and during its height, but more particularly during its period of decline and convalescence. The published cases have been recorded chiefly as instances of acute mania or melancholia. The commonest type of grippé mental disorder, as I have just stated, is a form of melancholia or lypemania; but as this not infrequently assumes the form of melancholia agitata, it is often regarded as mania by practitioners not accustomed to differentiate the varieties of insanity. These patients are intensely depressed and emotional; they are filled with apprehensions of disgrace and ruin; they believe that they will never recover their former health; they are suspicious and delusional with reference to those who surround them; they are frequently unwilling to eat, or to rest, or to take medicine; and in some cases they have definite delusions of terrible character, for the most part hypochondriacal or religious. They are frequently plagued with the thought of suicide, and sometimes make successful or unsuccessful suicidal attempts. They have been deprived by the ravages of the disease of mental and moral stamina. In the majority of these cases, but not in all, some hereditary or acquired predisposition is present. While, however, the grippé usually gives us mental disorder of special type—a form of delusional melancholia—under special conditions it may be the starting-point or exciting cause of any variety of mental disorder, as mania, paranoia, parietic dementia, hebephrenia, etc., but I can no more than glance at this phase of the subject.

The investigations of Church show that in each year in Cook County, Illinois, the epidemic of influenza has been attended by an increase in the number of proceedings for the commitment of the insane, which he believes can not be explained by increase or movement of the population of the county.

Of the influenza occurring in hospitals for the insane, I have had no opportunity for observation except in connection with the insane department of the Philadelphia Hospital. A great disproportion has been observed between the number of cases occurring among the women

and the men. One hundred cases are recorded as having occurred among four hundred and sixty female patients; and only three in a larger number of men. The disease did not prove particularly disastrous among these patients, only three deaths having occurred from pulmonary complications. The cases were, as a rule, not of severe type; less severe than in an equal number of sane patients.

K. Helweg\* has recorded the results and action of influenza in the Asylum at Aarhus, Denmark, and Pritchard has translated and summarized this paper for the *Review of Insanity and Nervous Disease* for December, 1891. The account is of such interest that I will give it in detail: "The disease appeared in the asylum January 4th, a few weeks after it had first been observed in the neighborhood. Out of 520 insane, 41 were so severely attacked that they were confined to their beds. The disease seemed decidedly contagious. It spread with difficulty on account of the wards being divided one from another. Eight of the twenty-five wards were spared altogether. When a ward would be invaded, the disease would rapidly run its course to proceed to another. The transmission of the contagion could be distinctly seen in the sick wards where those stricken down in the other wards would bring the disease with them and transmit it to patients there. Seven patients had pneumonia. A relatively large percentage (six) died, of which four were from pneumonia. Among these was a man with such a severe cerebral disease that he must be excluded (the post-mortem results in the remaining five, which were women, were all more or less similar). The most essential results were extreme hyperæmia of the cranial bones and membranes, where the dura and the brain mass itself twice presented fresh and strongly vascular pseudo-membranes with small hæmorrhages as well. The veins and arteries of the thinner cerebral membranes were filled to bursting with blood; the large basal arteries were so filled with coagula that they stood out like cords, or those of an injected specimen. The brain substance itself was very hyperæmic, and its consistence increased. The average weight of these brains was about the ordinary of those of Aarhus. The writer also gives the history of the man mentioned, and those of the three other cases where influenza could not be diagnosed during life, including the post-mortem findings of a case of influenza in a (sane) nurse who died of pneumonia. Here also was great hyperæmia of the brain and its membranes, yet not so pronounced as in the insane cases. The writer has seen influenza accompanied by severe psychic symptoms. In a few cases the condition resembled acute delirium, which, however, is transient, and seems easily controlled by antifebrine. On the contrary, in two hopeless cases of insanity the disease had such a favorable and curative action that they may be regarded as cured. In both cases there was pneumonia."

The epidemic influenza has impaired the *morale* of the community. Lack of spirit in work, and an apprehensiveness with reference to health, business, and all matters of personal interest, are abnormally prevalent. The hysterical have become more hysteric; the neurasthenical more neurasthenic. Hypochondria has displaced hopefulness in individuals commonly possessed of courage and fortitude. In brief, certain neuropathic and psychopathic features have been impressed upon the community. We can not afford even to dismiss entirely from consideration the bearings of the epidemic upon the increase not only of suicides, but of other grave crimes.

Many interesting questions in connection with treatment might be discussed; but as the subject of treatment has been assigned in this discussion to Dr. Hare, I will only speak of one point.

The use in influenza of hypnotics, narcotics, sedatives, and motor depressants is a question of particular interest in connection with the study of the nervous and mental phenomena of the disorder. The views of practitioners and writers are here decidedly at variance. Serious mental and nervous complications or actual insanities occurring during influenza have been attributed to the too free use of such chemically powerful remedies as ihenacetin, antiptyne, antifebrine, chloral, bromides, sulphonal, and paraldehyde; and our older narcotics—such as opium, hyoscyamus, conium, and cannabis indica—have also come in for a share of blame. Persisting conditions of nervous prostration, and

\* Savage. *Lancet*, No. 3558; and *Medical News*, January 16, 1892.

\* Helweg. *Hosp.-Tidende*, R. 3, Bd. viii, S. 729.

chronic respiratory and cardiac neuroses, have also been charged to drugs. Undoubtedly such criticisms have some foundation, but it remains true that each of the remedies named has proved itself of some value in the treatment of influenza, and particularly of its nervous types. The enormous consumption of a drug like antipyrine is a practical argument both for and against its use. What Grasset has said of this remedy might with almost equal truth be said of almost any of the rest. "This agent," he says, "vaunted by some as a panacea against all manifestations of the disease, is considered by others a remedy absurd and irrational in all cases. The truth would seem to reside between these two extreme opinions."

**The Influenza Bacillus.**—The *British Medical Journal* for January 16th contains the following articles, translated from advance proof-sheets of the *Deutsche medicinische Wochenschrift*:

*I. Preliminary Communication on the Exciting Causes of Influenza.* By Dr. R. PFEIFFER, Chief of the Scientific Section.—(From the Berlin Institute for Infectious Diseases.) The following results are based on the accurate examination of thirty-one cases of influenza, in six of which a necropsy was made. A complete report will be published as soon as possible.

1. In all the cases of influenza a bacillus of a definite species was found in the characteristic purulent bronchial secretion. In uncomplicated cases of influenza these tiny bacilli were found in absolutely pure cultures, and mostly in immense quantities. They were very frequently situated in the protoplasm of the pus corpuscles. If the influenza had attacked persons whose bronchial tubes were already otherwise diseased—as, for example, phthisical patients with cavities—other micro-organisms besides the influenza bacilli were found in the expectoration in variable quantity. The bacilli may penetrate from the bronchial tubes into the peribronchitic tissue, and even reach the surface of the pleura, where, in two cases examined post mortem, they were found in pure cultures in the purulent exudation.

2. These bacilli were found exclusively in cases of influenza. Very numerous control examinations proved their absence in ordinary bronchial catarrh, pneumonia, and phthisis.

3. The presence of bacilli kept equal pace with the course of the disease; with the cessation of the purulent bronchial secretion the bacilli began to disappear.

4. I had already seen and photographed similar bacilli in the same enormous quantities two years ago, during the first epidemic of influenza, in preparations of the sputum of patients suffering from the disease.

5. The influenza bacilli appear as very tiny rodlets, of about the thickness of the bacilli of mouse septicæmia, but only half the length of these. One often sees three or four bacilli strung together in the form of a chain. They stain with some difficulty with the basic aniline dyes. Better preparations are obtained with dilute Ziel's solution and with hot Loeffler's methylene blue. In this way it can be seen almost as a rule that the two ends of the bacilli take the stain more intensely, so that forms are produced which can only with great difficulty be distinguished from diplococci or streptococci. In fact, I am inclined to believe that some of the earlier observers also saw the bacilli described by me, but that, misled by their peculiar behavior with regard to staining agents, they described them as diplococci or streptococci. They can not be stained by Gram's method. In hanging drops they are immobile.

6. These bacilli can be obtained in pure cultures. On 1.5-per-cent. sugar agar the colonies appear as extremely small droplets, clear as water, often only recognizable with a lens. Their continued culture on this nutrient medium is attended with difficulties, and up to the present I have not succeeded in carrying it beyond the second generation.

7. Numerous inoculation experiments were made on apes, rabbits, guinea-pigs, rats, pigeons, and mice. Only in apes and rabbits could positive results be obtained. The other species of animals showed themselves refractory to influenza.

8. In view of these results I consider myself justified in pronouncing the bacilli just described to be the exciting causes of influenza.

9. It is very probable that infection is produced by sputum charged with the germs of the disease; and the disinfection of the sputa of

patients suffering from influenza is therefore urgently required as a prophylactic measure.

*Addendum.*—Dr. Kitasato has succeeded in cultivating the influenza bacilli to the fifth generation on glycerin agar.

*II. On the Influenza Bacillus and the Mode of cultivating it.* By Dr. S. KITASATO.—(From the Berlin Institute for Infectious Diseases.) Gentlemen: It is, perhaps, remarkable that in the case of a disease which in the last few years has attacked hundreds of thousands of persons, the specific exciting causes have, in spite of extremely numerous investigations, only lately been discovered. The cause, in my opinion, lies in the extreme difficulty of cultivating the tiny bacilli here before you; and, without pure cultures, a bacteriologist can not, of course, come before the public with a new specific micro-organism.

The difficulty of obtaining cultures of specific bacteria present in the sputum depends chiefly on the great contamination of them with micro-organisms from the mouth, etc. The latter, in consequence of their more luxuriant and abundant growth, can, on our artificial nutrient media, completely overgrow and hide the particular parasites sought for. This occurs all the more easily the longer the specific parasitic micro-organism in question takes to form colonies, as in fact happened in the case of the tubercle bacillus.

With the view of avoiding the obstacles standing in the way of a successful cultivation, Privy Councillor Koch has devised a method, which has not yet been published, which enabled him many years ago, and myself again quite recently, to obtain pure cultures of tubercle bacilli directly from the sputum, and which has also been followed by me in the pure cultures of tubercle bacilli here before you. The method to which I have just referred will be published in full detail in an early number of the *Deutsche medicinische Wochenschrift*.

With regard to the characteristics of the pure cultures of influenza bacilli here before you, I may emphasize the following points: On a sloping surface of set glycerin agar the individual colonies present themselves as extremely small points like droplets of water, recognizable during the first twenty-four hours only with the aid of a lens, so that macroscopically a test tube containing them can scarcely be distinguished from a sterile one. The individual colonies are, as has been said, so unusually small that they may easily be overlooked, and it may thus have happened that previous investigators have overlooked them.

If a culture obtained from such a colony is placed on a new nutrient agar medium, numerous small colonies arise on the moist agar surface, as may be seen in this tube. A particularly remarkable point about them is that the colonies always remain separate from each other, and do not, as all other species of bacteria known to me do, join together and form a continuous row. This feature is so characteristic that the influenza bacilli can be thereby with certainty distinguished from other bacteria.

The possibility of continued cultivation is now demonstrated, and the tubes here before you already form the tenth generation in pure cultures. On gelatin they do not grow, as they do not generally multiply at a lower temperature than 28° C., which is the temperature at which gelatin solidifies. In *bouillon* they grow scantily. In the first twenty-four hours single white particles are seen swimming in the *bouillon*, the intervening fluid being perfectly clear. Later, they sink to the bottom, and there form a white woolly mass filling the end of the test tube, whilst the supernatant *bouillon* remains entirely clear—a proof that we have to deal with an immobile bacillus. In conclusion, I may remark that I have accurately studied with the microscope and by culture for a long time back the sputa of tuberculosis in respect to all the micro-organisms occurring therein besides the tubercle bacillus, and also the sputa of pneumonia, bronchitis, etc.; but the present bacillus, so extraordinarily characteristic in its cultures, and so easy to be recognized, has not come within my experience except in influenza patients.

*III. On a Micro-organism in the Blood of Influenza Patients.* By Dr. P. CANON, Assistant Physician, Berlin.—[From the Municipal Moabit Hospital (Section of Internal Medicine—Director, Dr. P. Guttmann).] During the last few weeks I have, under the direction of Dr. Guttmann, examined the blood of twenty influenza patients in stained preparations, and in almost all cases I have found in the blood one and the same micro-organism. The examination of the blood was made in the following way: A drop of blood, obtained by pricking the finger, was

received on a perfectly clean cover-glass; this cover-glass was placed upon another one, and the two then drawn apart. The preparations, after they had been thoroughly dried, were placed in absolute alcohol, in which they were left for at least five minutes. They were then taken out and placed in the following staining solution (Czenzynke's solution):  $\frac{1}{2}$  Concentrated watery solution of methylene blue, 40 grammes;  $\frac{1}{2}$ -per-cent. eosin solution (dissolved in 70 per cent. alcohol), 20 grammes; distilled water, 40 grammes. The cover-glasses, immersed in this staining solution, were placed in an incubator at a temperature of  $37^{\circ}$  C., and left there from three to six hours, when they were washed with water, dried, and imbedded in Canada balsam. In the preparations of blood made in this manner where the red blood-corpuscles were red and the white ones blue, I found the above-mentioned micro-organism. It is found stained blue, sometimes in large quantities, but mostly sparingly, and only to be identified after a long search (about four to twenty in the preparation). Sometimes it appears as a small diplococcus, sometimes, especially when it is more deeply stained, as a short bacillus. In six cases I have found it also in numerous larger and smaller heaps of from five to fifty individual microbes with a very characteristic appearance. In these six cases the blood was drawn during a fall of temperature or shortly afterward; in three of these no further rise of temperature occurred. From three to six days later I failed again to find the micro-organism in the blood in these three last cases. Sometimes I have been able to make the diagnosis of influenza when clinically it was not certain, by means of preparations of the blood alone. I have also found the bacteria in the blood, and indeed in considerable quantities, in cases where there was no appreciable local lesion, and especially no cough or expectoration. While making the preparations I have generally at the same time made streak inoculations of the blood on agar, glycerin agar, sugar agar, and *bouillon*. In six cases the *bouillon* was injected into mice, partly at once, partly on the following day after it had been in the incubator. These inoculations and experiments on animals always yielded a negative result. As on the basis of my researches I am of opinion that this micro-organism occurs in the blood of all persons suffering from influenza (at least in that of those who have fever), and as it is not found in the blood of other persons, and as it is a micro-organism hitherto unknown, I believe that it stands in direct relation to influenza.

Privy Councilor Koch had the goodness to examine some of my preparations—for which I tender him my best thanks—and pointed out that the micro-organism visible in them was identical with the bacterium found by Staff-Surgeon Dr. Pfeiffer, which has been described in the preceding paper, which is published at the same time as mine. I began these researches about the middle of December; I have, however, still a large number of preparations to stain and to examine. I propose to publish the results of the further research in a later communication. I have to thank Dr. Guttman and Professor Dr. Sonnenburg, director of the surgical section of the hospital, for kindly placing patients at my disposal.

**The New York Academy of Medicine.**—The following is the present list of officers: Dr. Alfred L. Loomis, president; Dr. R. C. M. Page, Dr. E. L. Keyes, and Dr. Charles McBurney, vice-presidents; Dr. Richard Kalish, recording secretary; Dr. O. B. Douglas, treasurer; Dr. M. A. Starr, corresponding secretary; Dr. Everett Herrick (chairman), Dr. Gouverneur M. Smith, Dr. Abraham Jacobi, Dr. Laurence Johnson, Dr. F. A. Castle, and Dr. W. F. Cushman (treasurer), trustees; Dr. T. R. French, chairman of the committee on admissions; and Dr. T. M. Cheesman, chairman of the committee on the library.

The special order for the meeting of Thursday evening, February 4th, was a paper by Dr. J. West Roosevelt, entitled *Practicable and Impracticable Plans for diminishing the Spread of Phthisis Pulmonalis*.

**Section in General Surgery.**—Dr. J. D. Bryant is the chairman, and Dr. W. W. Van Arsdale the secretary. At the next meeting, on Monday evening, the 8th inst., Dr. T. H. Manley will read a paper on *Primary Amputation, Consecutive Amputation, and Resection in Traumatism of the Extremities*, and will show patients illustrating the subject; Dr. R. H. M. Dawbarn will read a paper entitled *Experience*

with Senn's Hydrogen Gas Test for Wounds of the Gut, and show a patient illustrating a cutting operation for the relief of an old dislocation of the inferior maxilla; and Dr. C. A. Powers will show specimens of an elbow joint two years after resection, of a conical stump (physiological) from a child of three years, and of melano-sarcoma of the lower jaw from a child of four months.

**Section in Paediatrics.**—Dr. W. P. Northrup is the chairman, and Dr. F. M. Crandall the secretary. At the next meeting, on Thursday evening, the 11th inst., papers pertaining to the management of diphtheria will be read by Dr. J. E. Winters, Dr. H. D. Chapin, Dr. L. E. Holt, and Dr. Abraham Jacobi.

**Section in Genito-urinary Surgery.**—Dr. E. L. Keyes is the chairman, and Dr. Samuel Alexander the secretary. At the next meeting, on Thursday evening, the 11th inst., papers (titles to be announced) will be read by the chairman and by Dr. Otis.

**Section in Ophthalmology and Otology.**—Dr. T. R. Pooley is the chairman, and Dr. J. E. Weeks the secretary. At the next meeting, on Monday evening, the 15th inst., Dr. J. H. Claiborne will read a paper on *The Axis of Astigmatic Glasses*, and Dr. R. C. Myles will read one on *The Normal and Pathological Anatomy of the Ear*.

**To Contributors and Correspondents.**—*The attention of all who propose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

## Original Communications.

CLINICAL OBSERVATIONS ON THE  
TREATMENT OF TRACHOMA BY EXPRESSION.

BY THOMAS R. POOLEY, M. D.,

NEW YORK,  
PROFESSOR OF OPHTHALMOLOGY IN THE NEW YORK POLYCLINIC;  
SURGEON-IN-CHIEF TO THE NEW AMSTERDAM EYE AND EAR HOSPITAL.

AMONG the most unsatisfactory cases to treat in the whole domain of ophthalmic therapeutics, trachoma may justly be placed in the very front rank, and any plan of treatment which will shorten the chronic duration of this disease must be considered a boon. That this has been accomplished by the recent revision of an old plan of treatment, the experience of ophthalmologists both in New York and elsewhere, who have tried it in a large number of cases, would seem to show, and the evidence that it cuts short the progress of these cases to a wonderful degree is fast accumulating. This much may fairly be said without running the risk (as is too often done in our enthusiasm) of being too sanguine about any new method of treatment. The purpose in this communication will be to set forth as concisely as possible the results obtained by the operation in a few cases, with such observations as the experience thus obtained would seem to suggest. These cases embrace all those operated on by this method since November, 1890, a period covered by one year, and in all cases only those were selected which seemed especially applicable to this method—*i. e.*, acute cases which showed a disposition to become chronic, and where the trachomatous bodies are more or less numerous, with but little irritation and moderate inflammatory reaction.

The method is not applicable to the third stage of trachoma, usually known as diffused, in which another one known as *grattage* is now employed by some operators. The cases from which the writer's experience has been gathered embrace but a limited number; nevertheless, they have all of them been followed to their ultimate conclusion, and afford, therefore, a good criterion of the results to be obtained by this method of treatment. Seven patients and ten eyes were operated upon. In all except one the patient was placed fully under the influence of ether; in one cocaine alone was made use of, while in several others cocaine as well as ether was employed. When ether alone is used the hæmorrhage is more profuse than when cocaine is also employed.

Most operators employed specially constructed forceps. At a recent discussion in one of the medical societies nearly all present had one of their own invention to show. That these are sometimes advantageous can not be denied, but the author greatly prefers for the expression of the contents of the granules to use the fingers and the thumb-nails, which should be thoroughly cleansed and scrubbed with a nail-brush. The lids are everted and then the granules squeezed out by the thumb-nail aided by the index finger in the *cul-de-sac*, or else both index fingers may be used, the left beneath, and the right—which does the most work—above the lids. The application of this method is especially difficult

in the angles, where the use of forceps may be needed, in which case either the forceps invented by Dr. Noyes or an ordinary cilia forceps was made use of.

The success of the operation depends upon the thoroughness with which every granule is expressed, or emptied of its contents, and is therefore an exceedingly tedious procedure. The eyes must be frequently cleansed during the operation by a solution of boric acid or bichloride of mercury. In six cases, after the lids had been thoroughly cleansed and dried, their surfaces were rubbed over very thoroughly with a crayon of sulphate of copper, as recommended by Dr. Gruening. In four cases this was omitted. At first the patients were always kept in the hospital for two or three days after the operation, but as more knowledge was acquired by experience as to the nature of the reactive processes, they were in some cases, where there were objections to this, allowed to return home. Cold compresses often changed were applied over the lids for about twenty-four hours—in some instances longer—to combat the reaction, which was usually severe, and in one case even threatened the destruction of the eye. It was usually, however, confined to swelling and œdema of the lids, which, under the use of cold compresses, rapidly subsided, and was always the most severe when copper was used. In a few days after the operation, if all the granulations had been expressed, no appearances of trachoma remained, but a good deal of conjunctival swelling and secretion, which continued for some time, gradually subsided, leaving the lids in a comparatively healthy condition. All of the cases were practically cured in from three to five weeks, except one in which there was dense corneal pannus and a good deal of reaction from the treatment as well; this case will be reported in full as Case III, and is the only one of the series in which the cornea was affected or the sight impaired; in all the others the disease was confined to the lids alone. In all but one instance only one eye was operated upon at a time. The experience of the operator in the one case where this was deviated from will probably deter him from repeating it again. Without going into a tedious detail of all the cases, it may be of interest to give briefly the notes of several, and a more extended account of the case in which the character of the reaction was alarming.

CASE I.—Anna Y., aged nine years, left eye operated on in the New York Polyclinic, November 20, 1890, under ether. Both lids, especially the lower, were studded over with large, fresh, spawn-like granulations, and were squeezed out by Noyes's forceps and the finger-nails, care being used to attack all the granulations. The upper lids operated in the same manner, but they were not so abundant. After the evacuation of all the granules the surfaces of the lid were thoroughly rubbed over with sulphate of copper in crystal. Patient was sent to the New Amsterdam Eye and Ear Hospital; cold applications made. There was but little reaction swelling of the lids and œdema. Right eye operated on in the same manner November 21st, but the expression was entirely accomplished by the use of the thumb-nails and fingers. There was a more brisk reaction than from the first operation, but under the same treatment it soon subsided, and November 23d the patient left the hospital. She was under treatment for about two weeks more in the dispensary, and then dismissed entirely cured.

CASE III is the one in which there was such excessive reaction.

Mary M., aged fifteen years, entered the New Amsterdam Eye and Ear Hospital March 18, 1891, with trachomatous pannus, and the upper lids, which were especially affected, studded over with large, fresh granulations. The granulations were less abundant in the lower lids. There was dense pannus of both corneæ, and vision was reduced to counting fingers. She had been practically blind for two years, and had already had the lids operated, probably by expression. With the patient thoroughly etherized, the granulations were expressed, in the manner already described, from both eyes, and then their surfaces rubbed over with the copper stick. The following morning, notwithstanding the use of cold compresses, both lids were terribly swollen, tense, and brawny, as seen in diphtheritic ophthalmia, so that it was almost impossible to evert them, on accomplishing which their inner surfaces were covered by a croupous-looking membrane, which could be detached with difficulty. Both corneæ were infiltrated, and in the left there was a deep ulcer. Cold applications were continuously applied both during the day and night until the next morning, reducing very greatly the excessive swelling of the lids, and atropine used as well.

November 20th.—There is now an ulcer of the right cornea as well, while that of the left seems about to perforate. A solution of eserine, one tenth of a grain to the ounce, was instilled every two or three hours, and atropine three times a day, while warm applications, fifteen minutes at a time three times a day, were substituted for the cold ones. She now began to improve rapidly, the corneal ulcers, which fortunately were not central, healed, the corneæ cleared, and she could see much better than before the operation.

March 28th.—She was discharged. Right eye, V. =  $\frac{5}{200}$ . L. V. =  $\frac{18}{200}$ . She came from this time on until April 7th to the clinic, and there was continued improvement without any further treatment. Vision rose to  $\frac{20}{200}$  in the right and  $\frac{27}{200}$  in the left eye. The lids were almost entirely free from any appearances of trachoma.

CASE IV.—Mary S. entered the hospital May 1, 1891, with recent trachoma of both eyes. The granulations were abundant, fresh, and covered the entire lower *cul-de-sac* of both eyes, the upper lids being comparatively free. The left eye was operated on in the same manner as already described, the operation followed by very considerable swelling and œdema of the lids, rapidly subsiding under the continuous use of cold applications. On May 3d the right eye was operated upon, and in like manner followed by a good deal of swelling of the lids, which, however, soon subsided. The patient was discharged May 10th, made thereafter occasional visits to the clinic, and was dismissed from treatment with the trachoma quite well in about three weeks.

To sum up the advantages of this method of treating trachoma, it seems not too much to say that by it we can cure in a few weeks cases which, under the old plan by the use of nitrate of silver and sulphate of copper, would last for months and years, and this, too, by an operation which is comparatively free from danger. The success of the operation will, no doubt, be in direct relation to the thoroughness with which it is done. Although many of the granulations may be absorbed by the reaction consequent upon the operation, still, should some of these remain, there will still be trachoma to some extent which may spread again over the whole conjunctiva. And it may even be necessary to resort to a second operation.

The operation in which the sulphate of copper is used

gives the best results, although a cure may be effected without it if care is taken to be thorough in the expression of the contents of all the granulations. It is desirable to operate upon only one eye at once, because of the possible dangerous reaction when both are done at once; besides, the operation, if carefully done, would be too tedious and long an operation. The treatment by this method is far less dangerous than inoculation of pus, sometimes practiced in severe cases of trachoma, and is also less dangerous and more efficacious than the treatment by jequirity. We may therefore hope that at last we have a means of effectually combating this hitherto intractable disease—and that our hospitals and dispensaries will soon cease to be crowded by the daily attendance of chronic trachoma patients—by a procedure which not only arrests but cures the disease in its first stages.

That the old cases—those which have been modified by a long course of treatment with caustics and diffused trachoma—will as readily be cured by the operation of grattage does not seem to the writer as probable; but should this be so, we shall then have at our command two procedures which will render us masters of the situation.

## THE PROGRESS OF CYSTOSCOPY IN THE LAST THREE YEARS.

BY WILLY MEYER, M. D.,

ATTENDING SURGEON TO  
THE GERMAN AND NEW YORK SKIN AND CANCER HOSPITALS.

(Concluded from page 146.)

### III. CYSTOSCOPY WITH REFERENCE TO DISEASES OF THE KIDNEY.

NITZE, Fenwick, Goldschmidt, Poirier, Tuffier, Janet, and many others have published interesting cases where negative vesical evidence gave a positive diagnosis of renal disease and where cystoscopy not only proved the formerly obscure trouble to be of renal origin, but gave the means for exactly locating the lesion and distinguishing which kidney is diseased or whether both are affected.

Under ordinary circumstances it is not difficult to determine whether the urine propelled from the ureteral cones is clear, murky (purulent), or bloody. We simply have to place our prism just opposite and comparatively close to the mouth of the ureter, and then carefully watch. Some experience and patience, a quiet hand, and close attention are all that is needed. But, as mentioned above, this task at once grows more difficult if the injected clear water rapidly becomes turbid. The inspection can then only be effected by means of the irrigating cystoscope.

CASE I. *Pyuria; Cystoscopy; Nephrotomy; Nephrectomy; Recovery.*—Mrs. X., aged forty-five years, had noticed since several years that her urine was now and then cloudy; had also occasionally experienced some pain in her left side. The latter was attributed to a fall the patient had received while out sleigh-riding in the country twenty years ago. Otherwise she had always been in apparently good health. At the middle of June this year she was suddenly taken very sick with high, continuous fever, enlarged spleen, and general symptoms, which were suspicious of typhoid. But a tumor was palpated in the left

lumbar region, and the urine contained pus. The gentleman who had been consulted proposed cystoscopy, and I was called in to perform it. After a short irrigation the water returned clear. Quickly the elements of the battery were screwed down into the acid, the full strength of the current allowable for getting a bright light determined, and the circuit broken. The catheter, corked, had been left in the bladder meanwhile. In extracting it then a few drops of water escaped, perfectly turbid. Of course only renal trouble could have done that. Again the fluid in the bladder was changed and the irrigating cystoscope introduced. One glance in bright illumination, showing a healthy bladder; and a dense fog suddenly came up and threw a heavy veil over the whole landscape. Now the irrigating cystoscope was put at work. The prism was turned to the left and the murky fluid allowed to run off, while the hand-syringe threw in short jets of clear water. The fog lifted, and I clearly perceived the left ureteral opening, and out of it nearly at the same moment a forcible eruption of a snowy-white, milky fluid. Spurting forward into the medium, which was contained in the bladder, in the shape of a fire-sheaf, the first rather thick mass at once dispersed and was dissolved into myriads of minutest snow-flakes, which slowly came down and at once put a stop to all further examination. The manœuvre was now repeated on the same side and the diagnosis of suppurating kidney clearly established. The very frequently descending jets, which always are pathognomonic of an irritative process in the pelvis of the respective kidney, could be attributed to the coexisting pyelitis or the presence of a stone in the pelvis. Of course the urine of the right kidney was now analyzed in the same manner. It was clear.\* A few days later I performed nephrotomy and found a pyonephrotic kidney with a large stone in the greatly enlarged pelvis. Only the debilitated condition of the patient prevented me from removing the diseased organ at once. Primary nephrectomy seemed to me to be fully justified in view of the cystoscopic result, and would have spared the patient a second operation. The kidney was, however, left in and drained, with the intention of extirpating it as soon as the lady's health would permit it. Nephrectomy was done by me four months later, on account of an annoyingly running renal fistula. To-day the patient is cured.

A number of patients with intermittent abundant hæmaturia have been under my care in whom the cystoscope demonstrated a perfectly healthy bladder. In only one of them have I been so lucky as to make the examination just at the time of the bleeding, and I then saw a red, rapidly propelled whirl crossing the prism, and slowly mix with the transparent water, slightly coloring the same. None of the patients, who just happened to be examined at the bloodless period, reappeared at the time of the next hæmaturia as ordered. Perhaps they were unable to come. The one in whom I had diagnosticated unilateral renal hæmaturia—which, according to the symptoms, was evidently caused by a new growth—declined the proposed operation. She died after an abundant hæmorrhage not long afterward. A few cases of this kind are published by Nitze, Fenwick, and others.

\* I want to state here that even with the able help of the irrigating cystoscope it is extremely difficult, if not in many cases impossible, to make out a urine which is only very slightly turbid or which is clear and contains long shreds of tissue, as I have seen it in one case. Generally a certain amount of turbidity is required before it becomes visually apparent and perceptible. Bimanual palpation of the suspected diseased organ or pressing it will frequently help in making the cystoscopic diagnosis of renal pyuria.

But the transparency, color, and frequency of the descending jets of urine are not the only points which have to be observed and noted in exploring the bladder with the electric light. We are able to still further analyze and specify the character of the whirls as they can be seen jetting from the ureters.

The history of a few more cases of renal disease, which lately occurred in my own practice, will well illustrate this.

CASE II.—*Cystoscopy; Suprapubic Lithotomy; Cystoscopy; Nephrolithotomy; Recovery* (the continuation of a case previously mentioned in this paper).\* On the 10th of March, 1891, Mr. D., of whom I had lost sight since the summer of 1888, again called upon me, a sick man. His stomach was entirely out of order. Every few days he vomited great masses of sticky mucus, and was only able to do so by first drinking a tumbler of very strong salt water. Cathartics were freely used. Entire loss of appetite. He had been for this trouble under a physician's care, who was, however, unable to improve his condition in spite of constant careful attendance. The doctor diagnosticated "nephrolithiasis on the left side" and sent the patient to me for operation. The history further revealed that not long after the suprapubic wound had definitely closed an attack of epididymitis on the right side had twice set in. The urine had never entirely cleared up. Last summer (1890) the left testicle became suddenly inflamed. At the same time, the former dull and constant pain in his left lumbar region, which had now and then troubled him during the entire last year, became more marked. For three days the urine was mixed with blood. A similar attack occurred in January, 1891. At present he had a constant pain and he was obliged to get up twice during the night to pass water. In the daytime he urinated about every four to five hours.

Cystoscopy (cocaine): Mucous membrane of the bladder comparatively healthy. No scar as a result of the operation visible. Prostate large, easily bleeding. Right ureter is pumping at regular, though rather short, intervals; ejects clear fluid. The whirlings propelled from the left ureteral opening are by far less frequent and last nearly as long as three of the opposite side combined. This phenomenon can be noticed with so much greater precision as the urine of the corresponding kidney is slightly turbid. No renal hæmaturia at present.

Considering all these facts, I diagnosticated "a stone in the pelvis of the left kidney large enough to partially block the upper ureteral opening." Taking this conclusion as correct, it was evident that the urine had to gather in greater quantity and had to distend the pelvis of the kidney more than ordinary before finding or rather making its outlet on one or more spots alongside the necessarily irregular surface of the stone. And this again explained best the curious character of the jets as observed at the left ureteral cone. Taking further into account that the patient had noticed his very first pain in the left lumbar region as early as 1886, and that I had to remove a stone from the bladder two years later, my diagnosis was well founded that nephrolithiasis had been the primary and constantly persistent trouble in this case. No doubt a small piece of the renal calculus had been broken off as early as 1886 and carried down to the bladder, and had there formed the nucleus of the stone which was removed by me in 1888. Was the other kidney healthy? I did not venture to answer this question on the ground of the cystoscopic result. Certainly the abnormal rapidity of the jets was suspicious and

\* Read before the Section in Genito-urinary Surgery of the New York Academy of Medicine, November 12, 1891, the patient being present.

pointed to an irritation in the pelvis of the right kidney. But the answer to this question was less important, as only nephrotomy on the left side seemed to be indicated.

I told the patient my diagnosis, and also my hope of being able to help him by operative interference. But, to confirm what I had just seen, I asked for a second cystoscopic examination. The patient at once agreed. When he returned for this purpose, he reported that in walking home from my office the other day he had felt a sharp pain in his right side. This had at first frightened him very much. But, as the pain had not reappeared, he felt easier now. The second cystoscopic examination fully corroborated the result of the first one.

Nephrotomy was proposed and accepted. On May 5th, this year, I made the lumbar incision. A large stone, entering the ureter for some distance, was felt as soon as I was down on the kidney. The pelvis was transfixed with two silk threads which afterward served as holders, and then incised between them in the length of fully an inch and a half. To extract the stone in one mass proved to be impossible. I broke it with my fingers by pressing upon the upper portion of the ureter from outside. Then I was able to pull the two pieces out with an ordinary dress-

FIG. 3.

ing forceps, the larger upper portion from the pelvis of the kidney and the more slender lower one from the ureter. The whole stone presented a perfect cast of the enlarged pelvis of the kidney and the upper part of the ureter. Its lower pole was flattened, in a shape not unlike the mouthpiece of a flute. It is in all two inches long (see Fig. 3). Now I pushed a long thin rubber bougie down the ureter, and then a small-sized soft-rubber catheter cut off at its end, through which I flushed a syringeful of warm boric water into the bladder. The ureteral canal evidently was free. Still I carefully palpated with a curved steel sound the interior of the kidney from the pelvis upward. No other concrement was found.

Meanwhile great care had been taken not to tear the cut surfaces of the pelvis of the kidney by pulling too hard on the silk threads which held it apart, as such a tear generally produces urinary fistula. Now the wound of the pelvis was closed with six catgut stitches, which did not include the mucous membrane, and the wound loosely packed with iodoform gauze. A small-sized short drainage-tube led down to the sewn-up wound in the pelvis of the kidney. The outer wound was closed with silkworm-gut threads which were only loosely tied.

The patient made an uninterrupted recovery. He never was feverish. Gauze and drainage-tube were removed after forty-eight hours. Leakage never set in. The wounds healed by primary union throughout. The patient left the hospital with the wound firmly closed on May 21st, sixteen days after the operation.

When I saw him again he reported that, four days after having returned to his home in Brooklyn, he was suddenly seized with a very intense renal colic on the right side—that is, the side opposite to the diseased kidney—which lasted six hours. The pain was so severe that the attending physician had to administer chloroform for a full hour. When the pain began to subside, he passed about ten ounces of urine at two times inside of an hour. Since that accident he was free from pain. Only the stomach was still troublesome. He soon left for the country, where he spent the summer. Lately a throat specialist has burned his nose and throat, which, according to the patient's statement, has greatly improved the still slightly rebellious stomach. A fortnight ago he passed, after some pain in his left

lumbar region, two round, semi-solid masses, each of a bean's size. This was from the side operated on. To-day he appears hale and hearty, fully able to attend to his business. He is entirely free from pain and trouble. His urine at present is clear. He, of course, has to remain under observation on account of the probable nephrolithiasis on the right side.

*CASE III. Suppurating Floating Kidney; Nephrotomy; subsequent Cystoscopy; Nephrectomy; Recovery.*—Mrs. X., forty-five years old, came under my care in July, 1887. Two months previous she had been operated upon for an inflammation which had set up in the left (floating) kidney. The lumbar incision had revealed a cystic degeneration of the organ, the cysts being filled with clear, transparent fluid or pus, or a mixture of both. A number of cysts were opened, and communication established between as many as could be reached with Paquelin's thermo-cautery. The pelvis of the kidney was not opened. The wound had healed well up to two small sinuses, which remained in the scar and gave a continuous exit to a small or larger amount of sero-pus. The patient was greatly benefited by the operation. For more than two years she felt comfortable and enjoyed life; only at the time of menstruation she suffered from more or less intense bladder tenesmus. But after a while this symptom ceased to be limited to the menstrual periods and became nearly constant. It increased in such a degree of severity and frequency, in spite of manifold and persevering trials to fight it, that life was a misery, and the question came up, Could the patient still be improved by operative interference? Of course, this question had been frequently considered at length before, but it was always rejected in view of the clinical fact that cystic degeneration of the kidney very rarely is a unilateral disease. Usually both organs are involved.\* Cystic degeneration is therefore rather a contra-indication to nephrectomy. And indeed in this case the lower pole of the right kidney was palpable in the right hypochondrium. But could this enlargement of the organ not be just as well due to compensatory hypertrophy, in view of the constantly diminishing size of the left one, which had always been easily palpable in the slim patient? If we could know that the right kidney had already assumed the work of the other or that the secretion of urine from the left diseased organ was insignificant in comparison with that of its fellow, the patient could only be benefited by the removal of this nearly useless cystic mass, provided that she stood the operation. That the greatest amount of pain and trouble was dependent upon the presence of the left kidney could be proved by vaginal palpation of the ureters. The left ureter presented a cord as thick as a thumb, the slightest compression of which created at once an urgent and painful desire to urinate; the right one was perceptible merely to the normal degree. Pressure upon it did not irritate the bladder.

Active treatment, however, became imperative when in November, 1890, chills, followed by high though short-lasting fever, repeatedly set in, apparently due to progressive ureteritis. To determine the exact condition of the right kidney it was, of course, very tempting to compress the left ureter, or even drain it for some time from the vagina. Either of the procedures however, would have required narcosis, which, if possible, had to be avoided.

\* Cf. O. Riegner. *Exstirpation einer wandernden Cystenniere Deutsche med. Wochenschr.*, 1888, No. 3.—Clark. Case of Cystic Kidney in which Nephrectomy was performed. *Glasgow Medical Journal* 1889, p. 177.—Newman. A Case of Cystic Disease of the Kidney diagnosed during Life. *Ibid.*, 1889, p. 255.—C. A. Ewald. Ein Fall von totaler cystöser Degeneration beider Nieren beim Erwachsenen nebst Bemerkungen zur Klinik dieser Erkrankung. *Berlin, klin. Woch.*, 189: No. 1.

I now resorted to cystoscopy and saw the following condition: Catarrh of the bladder, minutest and larger blood-vessels injected. The place where the orifice of the left ureter should be seen presented a succulent and curiously folded growth—viz., the swollen and inflamed fold of mucous membrane belonging to and surrounding the ureteral opening, the whole mass resembling a large lamp-shade. Still looking at the picture with interest and trying to find the mouth of the ureter, I suddenly noticed a jet of fluid, mixed with smaller and larger yellow flakes and shreds, which came from a somewhat retracted spot, a little to the left from the top of the mass. This exactly recalled the appearance of an eruption of a volcano, as drawn by the pencil of the artist. A few minutes later a long thread of thick, yellow pus was slowly making its way out of the same opening into the bladder. It took some time before I found the other, rather rounded, ureteral opening, a portion of normal though deeply injected mucous membrane, about three quarters of an inch in length, being interposed between it and the swelling just described. At this moment I had to stop the examination, which was made under local cocaine anaesthesia, as the weak patient felt rather tired. A short time later the bladder was again illuminated, this time with the intention to determine, if possible, the character of the jets descending from the *right* kidney. The ureteral orifice was quickly found and carefully watched. This orifice was pushed forward and retracted alternately, as we see it normally with each jet of urine thrown into the bladder. The regularity and frequency of this intermittent movement markedly contrasted with the slow and irregular working done on the other side. It struck me whether this symptom might not be used in finding out the exact amount of work done by each kidney. So I asked the assisting nurse to look at the watch and carefully count the time between my saying "Now," which marked each jet. I noted a passage of every twelve, fifteen, twenty, twenty five seconds on the right side, while on the other only every four, six, eight minutes, the period of the emission of the jet besides covering a somewhat longer time on the right than on the left side. Meanwhile the water had become muddy. It was easily changed, as I performed the examination with the irrigating cystoscope, and now I also perceived that the urine of the right kidney was clear.

What conclusion could I draw from these facts? I believed this: that the right kidney was doing from twelve to sixteen times as much work as the left one.\* Was I therefore justified in pronouncing the right kidney healthy? I did not venture to make such a definite diagnosis, especially in view of the frequent bilateral affection in cystic degeneration of the kidneys. The urine might be at times transparent, while at others turbid. Only often-repeated cystoscopy might possibly have cleared up this part of the diagnosis.

But to diagnosticate health or disease of the right kidney was not the main question. The question really was: "Would the work of the right kidney be sufficient if the left had been removed?" That it would be so seemed to be amply proved by the cystoscopic examination, and if it did, the diseased organ, which caused the repeated weakening attacks of ureteritis and septic fever, was a burden to the organism and could and should be removed.

On these grounds a favorable prognosis was made in regard to nephrectomy in its future results, provided the immediate effects of the operation were well borne.

I therefore performed the operation, and the specimen thus

obtained showed that only the lower third of the organ contained secreting tissue and that the upper two thirds consisted of cysts, smaller and larger in size, more or less communicating. In one of them there was a very small round stone. The whole organ was greatly diminished in size.

In the first twenty-four hours after the operation urine was scarce on account of the loss of blood. From the second day on the daily average quantity was thirty to forty ounces. The former chills and fever ceased at once. The patient made an uninterrupted recovery, and is so far greatly benefited by the operation.

CASE IV. *Left Suppurating Kidney; Cystoscopy; Nephrectomy; Recovery.*—Mrs. P. M., aged forty-eight years, was sent to me from Collinsville, Conn. Her father had died of phthisis. She had had eleven children, of whom seven were still living. For fourteen years the urine had been muddy and of offensive smell. Tenesmus changing in severity toward and after the end of micturition. Two years ago pains in the left lumbar and hypochondriac region appeared; the urine became of a milky color, and had lately contained small particles of coagulated blood. It was voided ten to twelve times in the day-time and at least four times during the night. The patient had continuously lost flesh and felt very weak. December 18, 1890, examination: On deep pressure below the border of the left false ribs, a hard, not very large, mass can be palpated, which is rather immovable, painful to the touch, and of apparently smooth surface. Vaginal exploration reveals a thickened left ureter, which, if compressed, is quite painful and creates the desire to urinate. On the left side of Douglas's *cul-de-sac* an enlarged, painful, immovable swelling (probably the ovary); urine of neutral reaction; smells very offensively; two thirds of volume sediment; shows pus and mucous cells, a few red blood-corpuscles, micro-organisms of great variety, crystals of oxalic acid and ammonium phosphates; detritus; one-per-cent. albumin in the filtered specimen.

Could this evidently suppurating left kidney still be removed? Did it still partake in the secretion of urine? Were both kidneys diseased?

Cystoscopy under cocaine: Mucous membrane of the bladder hyperæmic, and around the left ureteral orifice papillomatous in appearance. Out of the latter a very long, worm-like, under the electric illumination snow-white, shining thread of thick pus of the size of a thin pencil is very languidly making its way at short intervals. No jet whatever. The pus evidently was very viscid, as the long strings settle and curl in the bladder fundus—a very characteristic picture, which was also plainly noticed by a number of gentlemen present. It took some time before the medium became muddy. The right ureteral orifice was occupied by a round red growth of the size of a cherry. On putting the prism quite close to it, it appeared transparent. It consisted of mucous membrane (prolapse of the ureter). Out of its left (median) side jets of seemingly clear urine were thrown at short intervals.

Cystoscopic diagnosis: "Left suppurating kidney. Its secreting tissue entirely gone. Right kidney already does double duty for its destroyed fellow. Some irritation in the pelvis of the right kidney."

On account of this cystoscopic diagnosis I proposed nephrectomy. The operation was done by me at the German Hospital, December 29, 1890. It was found that the whole greatly enlarged left kidney was sclerosed and did not present a bit of normal secreting tissue. It contained many cavities communicating with its pelvis. A large ramified stone entered a number of them. After the operation the amount of urine never varied except in the first twenty-four hours. The patient made an uninterrupted recovery up to the thirty-ninth day, when she was

\* I think this is the first time that this kind of observation has ever been used for determining the work done by each kidney, and that its correctness was afterward proved by the specimen obtained.

suddenly seized with intense right renal colic and abundant hæmaturia. After five days of serious, nearly hopeless, illness she passed a stone (an excellent *demonstratio ad oculos* of the pathognomonic correctness of prolapse of the ureter). From that moment on she was again well and remained well. To-day she is perfectly healthy; her urine absolutely clear.

These cases present the most interesting ones in which I have resorted to endoscopic examination of the bladder for the purpose of diagnosing disease of the kidneys. The last two cases especially are, I believe, of so much more value as not only did cystoscopy enable me to establish the indication for nephrectomy and to make the prognosis that this operation would most probably not interfere with the patient's general condition, apart from its possible immediate consequences, but the specimen proved in each case the correctness of the different important points thus made out.

The catheterism of the ureters, with the help of still improved cystoscopic instruments, will, I trust, soon be an extremely important and never-to-be-omitted factor in cystoscopy for renal disease. Its results will greatly reflect upon and vastly increase the value, correctness, and exhaustiveness of such a cystoscopic diagnosis. The catheterism of the ureters in this way will easily, simply, and happily solve the problem on which many an ingenious mind worked in vain, or at least without general and recognized success—namely, the bloodless, separate collection and analysis of the secretion of each kidney.

The only non-operative method which formerly could be applied to localize and diagnose a kidney trouble in the male,\* where a large swelling or growth in one of the hypochondriac regions did not at once show where to search for it, was by compression of the ureter. The attempts at solving this task have been very ingenious, but have not been generally adopted in practice.† Axel Iversen,‡ therefore, proposed to open the bladder above the pubes and then to catheterize each ureter separately. Fully appreciating the great value of this mode of procedure, and not looking at suprapubic cystotomy as being a dangerous operation, I am perfectly convinced that cystoscopy will ere long make it just as superfluous and unnecessary, in the majority of cases at least, as it has already made Sir Henry Thompson's digital exploration of the bladder in most instances.

Of course, I do not want to be understood as if I

\* In the female our non-operative diagnostic means in this respect have been more ample, however difficult to practice, for a number of years. Cf. G. Simon. thought that all exploratory operations would now become obsolete. It is obvious that there will still be a number of cases where obstacles will render the ocular inspection of the bladder and of the descending jets of urine impracticable; where an insufficient capacity of the bladder, purulent or bloody urine will make the electric illumination of the bladder resultless; where, I may add, the ureters can not be catheterized, because their orifices can not be found or approached. In such cases we, of course, have to operate for diagnostic purposes. But these cases will henceforth be exceptions and their number will still lessen with the advance of this endoscopic branch, with the increased dexterity and experience of the cystoscopist, and with the additional construction of a really useful cystoscope for catheterism of the ureters.

In closing my remarks I offer the following conclusions:

1. In all obscure reno-bladder diseases cystoscopy has to be practiced, if necessary repeatedly, before operative interference for diagnostic purposes is resorted to.
2. There are a number of causes which make cystoscopy impracticable.
3. Cystoscopy is an easy and harmless examination; but its successful employment requires experience.
4. It should be performed as a *dernier ressort* after all other well-known means for making a diagnosis have been exhausted.
5. If properly applied, cystoscopy will generally clear up an obscure disease of the bladder.
6. In most cases we can determine, with the help of electric illumination of the bladder, whether we have to deal with a disease of the bladder or of the kidneys.
7. We can thus find out whether there are two working kidneys, also whether only one of the two kidneys is diseased or both.
8. We shall most probably soon be able, perhaps, in the greatest majority of cases, after sufficient personal practical experience and with the help of proper cystoscopic instruments designed for this purpose, to catheterize the ureters and thus gather in a bloodless manner the urine from each kidney separately.
9. We can make out in certain cases by observing the character of the jets of urine, especially by *timing their frequency and duration* at the ureteral orifices, whether the other kidney is doing the work for the one which is diseased.
10. These facts will tend to make superfluous, in the majority of cases at least, a preliminary suprapubic or perineal incision for diagnostic purposes, as well as a nephrotomy performed for determining the action of the other (not diseased) kidney. They greatly widen and strengthen our means for making the indication and prognosis of nephrectomy.
11. With the aid of Nitze's newest instrument, the operating cystoscope, we may look forward to being able to carry on intravesical treatment under the direct guidance of our eyes.

## DISEASES OF THE URINARY APPARATUS.

By JOHN W. S. GOULEY, M.D.,

SURGEON TO BELLEVUE HOSPITAL.

(Concluded from page 153.)

PART I.—PHLEGMATIC AFFECTIONS.

SECTION II.—SPECIAL CONSIDERATIONS.

### XII.

#### CHRONIC URETHRITIS; ITS NATURE, CAUSES, PHYSICAL CHARACTERS, DIAGNOSIS, AND TREATMENT.

THE nature and treatment of chronic urethritis for a long time greatly perplexed physicians, because the several pathic conditions which give rise to persistent urethral discharges had not been sufficiently well studied, and because the characters and sources of the discharges were not ascertained. These discharges were found to be so refractory to treatment that many empirical methods were used with little or no effect. It would be a waste of space to enumerate the many modes of treatment that have been employed during the past century. In speaking of this obstinacy of chronic urethral discharges, Ricord said to his disciples: "After having tried everything, try to do nothing"; for experience had taught him that meddling treatment only served to aggravate the phlegmasia, which he had often observed to subside soon after the cessation of all medication.

Although some light was thrown by Gubler upon the differential diagnosis of some of the lesions that cause chronic urethral discharges, little attention was paid to the teachings of his excellent essay on the anatomy and phlegmasia of the bulbo-urethral glands, which show that when a persistent urethral discharge of a clear and very viscid

mucoid substance occurs, its source is surely in one bulbo-urethral gland or in both glands, but that when this viscid discharge is purulent there is chronic phlegmasia of the bulbo-urethral gland or glands. This clearly indicates that all urethral discharges are not necessarily signs of chronic urethritis. An acute urethritis may be cured and leave no other trace than chronic phlegmasia of a bulbo-urethral gland or of its duct. In some cases, instead of bulbo-urethral adenitis, chronic cryptitis is consecutive to acute urethritis; in these cases the discharge is very little viscid, but has the odor characteristic of the mucous secretion of the urethral crypts. In other cases chronic prostatitis or gonocystitis may be consecutive to the acute urethritis.

Mercier, who made a careful examination of the question of chronic urethritis, did much toward disseminating correct views respecting the pathology and treatment of this phlegmasia.

Next came the labors of Désormeaux, who demonstrated, with the aid of the urethroscope, true granular urethritis to be the most common cause of persistent purulent urethral discharge. From that time chronic urethritis has been very diligently studied, and other lesions have been discovered which give rise to chronic purulent urethral discharge, and at present the treatment is directed to the cure of the lesions that have been so well specialized.

NATURE OF CHRONIC URETHRITIS.—Chronic urethritis, attended with a slight muco-purulent discharge popularly named gleet, morning drop, military drop, etc., may be a termination of any of the acute types of urethritis, may begin as a benign urethritis, the first stage of the acute types, or may be developed far back in the urethra, be latent to the sufferer, and be discovered by the physician only by means of the urethroscope or of a microscopical examination of the urine. It should not be confounded with urethral blennorrhœa, true gleet. The difference between these two pathic conditions is worthy of note. Chronic urethritis is a phlegmasia of the urethral mucous membrane yielding a muco-purulent discharge, whilst blennorrhœa is the result of an excessive secretion of mucus by the urethral crypts or by the bulbo-urethral glands without the intercurrent of phlegmasic action, though it may sometimes be a sequel of phlegmasia. Frequent sexual erethism without copulation not infrequently causes a persistent blennorrhœa arising from excessive secretion of the urethral crypts and bulbo-urethral glands, the urinary meatus being constantly moist with mucus or with the very viscid secretion of the bulbo-urethral glands without admixture of pus. This is true gleet, unconnected with phlegmasic action.

The phenomenon, chronic urethral discharge, unless rightly interpreted, is likely often to lead astray both patient and physician. The inexperienced sometimes look upon chronic urethral discharge as always an indication of urethral stricture or of some sort of obstruction of the canal. A little reflection is sufficient to throw doubt upon such a view, if only on account of its want of proper qualification, a suitable qualification being to substitute often for *always*, and to say that chronic urethral discharge is often a sign of stricture, or is sometimes one of the early symptoms of stricture. Such a

view would be indisputable. It is well known that a chronic urethral discharge may emanate from (1) phlegmasia of the seminal vesicles, (2) of the prostatic follicles, (3) of the bulbo-urethral glands, (4) or of the urethral crypts, as well as from (5) a circumscribed or a diffuse chronic phlegmasia of the urethral mucous membrane. It may be asked, How are these several discharges to be distinguished? The answer is as follows:

1. The discharge from the seminal vesicles contains symplexia and spermatozooids. Either distinguishes it from all the other discharges, even though it be mixed with them.

2. The discharge from the prostatic crypts is turbid, milky, and sometimes contains many prostatic symplexia and is very slightly viscons.

3. The discharge from the bulbo-urethral glands is known by its extreme viscosity; normally it is of crystalline clearness, but becomes opaque when containing pus.

4. The discharge from the urethral crypts is known by its peculiar odor, which it imparts to semen and which is called the seminal odor.

5. The discharge from a veritable chronic urethritis is muco-purulent and characterized by the profusion of pus cells it contains.

Chronic urethral discharge, no matter what may be its origin, is generally a source of much unnecessary anxiety to the patient, who thinks himself the most sorely afflicted of all mortals, and is almost incessantly watching the drop which he believes is forever to reappear. Of course it does reappear as long as he continues to irritate the urethra by "milking the penis" to find the drop when he thinks it is too tardy in showing itself. The morbid mind of the patient sees in this drop a virulent poison with which he is infected and which he is liable to transfer to any woman with whom he has sexual relations, and he has a vague notion that this poison may cause almost any disease. A medical friend related a case illustrating the ludicrous degree to which is sometimes carried the idea that a chronic urethral discharge from the man is liable to cause grave disease in the wife. The patient in question had been repeatedly told that his urethral discharge, consisting of clear mucus, was not contagious, but he always doubted the correctness of the doctor's view. However, he finally married and his wife soon became pregnant, but on or about the fourth month the abdomen was so much more distended than it would be even at full term that an examination was made which revealed a large multilocular ovarian cyst whose extirpation necessitated an extended median incision. The anxious husband, who had attributed this condition to infection by his urethral discharge, watched the operation with much solicitude, not on account of its gravity but of the fixed idea that he might be the cause of the disease. When he saw the enormous tumor, he said that if it had been a small lump he would have blamed himself, but that then he could not believe it possible for such a little drop to produce a growth of this size in the short space of four months.

Nothing is too absurd for the conception of some of the sufferers from chronic urethral discharges. They listen credulously to the ignorant and mendacious dicta of crafty

and rapacious charlatans, while they are suspicious of honest physicians, and obstinately discredit rational advice and correct views. Many change their medical adviser as often as they do their erratic notions of the ailment which, owing to their own perversity, is destined never to be well. The difficulties experienced in the management of such cases are too well known to require extended commentary.

The ideas to be impressed upon the minds of patients suffering from chronic urethral discharges are: 1, That these affections are not contagious; 2, that virulent urethritis is generally cured within six weeks, but that in some instances several relapses occur, the last of which is almost certain to be followed by a slight but persistent muco-purulent discharge, liable even after four, five, or six months to increase so as to simulate an attack of acute urethritis, subsiding, however, in four or five days to the former few drops; 3, that not only is this chronic urethritis non-transmissible from the man to the woman, but, on the contrary, is most frequently aggravated by coition, even with a woman whose genitalia are sound and remain so after the coitus; 4, that the frequently reiterated assertion that a man who has once had virulent urethritis in his bachelor days, and marries years after the attack of urethritis, transmits "the gonorrhœal virus" to his wife, is without the slightest foundation; 5, that this irrational notion arose from belief in a "gonorrhœal virus similar to but not identical with the syphilitic virus"; and 6, that the correct view is that virulent urethritis is a local affection, and does not become constitutional.

#### THE CHIEF CAUSES OF THE PERSISTENCY OF URETHRITIS ARE:

1. *Disregard of hygienic precautions* during acute urethritis, or after its apparent cure. Sexual erethism of any kind, in thought or act, improper alimentation, the use, even moderate, of alcoholic or fermented beverages, over exercise, and excesses in general, all aggravate the acute type of the phlegmasia or, after it has begun to decline, cause its recrudescence, and finally the persistence of the stage of decline which constitutes chronic urethritis.

2. *Inappropriate treatment* of the acute types of urethritis—such as the so-called abortive treatment by injections of nitrate of silver in strong solution, or of strong solutions of any sort, by the abuse or the untimely use of balsamics, antiphlogistics, diluents, and baths—is among the prominent factors in the causation of chronic urethritis.

3. *Vulnerability of the subject*—that is to say, an inordinate susceptibility to phlegmasia, owing to the hyperlithuria so common among chronic dyspeptics, or to some diathetic influence, besides a constitution naturally feeble or impaired by disease or debauch—may be added to the ætiological factors of chronic urethritis.

4. *Continued local irritation of the urethra* is another potent factor in the maintenance of urethral phlegmasia. This irritation may arise from frequent coition, from masturbation, from the existence of a stricture, from congenital stenosis of the urinary meatus, from vesical stones, chronic cystitis, chronic prostatitis, gonocystitis, hemorrhoids, anal fissure, eozema, etc.

5. *Excessive general and local treatment* of the acute types of urethritis both have the effect of prolonging the phlegmasic action—the first by disturbing the digestive function and enfeebling the patient and lessening his powers of resistance, besides causing grave complications. The large doses of balsamics long continued have a baneful effect upon the digestive apparatus, and often cause distressing cutaneous eruptions, hyperlithuria, and even nephritis. The too free use of alkaline diluents also tends to disturb digestion and otherwise defeat the objects for which these agents may be intended. The second, the untimely or the excessive use of urethral injections, is a prolific cause of the persistence of urethritis and of some of its complications and consequences. The too common tendency to treat the urethra as if it were not a part of the human body is owing chiefly to the want of proper interpretation of its morbid phenomena. It is over-distended, divulsed, or cut indiscriminately, simply because there is a discharge, and without ascertaining the nature of this flow. The idea that the discharge is a sure indication of the existence of a stricture is enough to induce the unthinking to over-distend, divulse, or cut the urethra. The patient, impressed with the notion that his case is unparalleled and demands extraordinary measures, consents to any proposed mode of treatment, even to the spilling of blood. He is then contented until he discovers that the urethral discharge is not cured by the operation, and that the drop still obstinately obtrudes itself.

**PHYSICAL CHARACTERS.**—The alterations of structure of the mucous membrane in chronic urethritis need to be studied during life by means of the bulbous bougie and the urethroscope, as well as by dissection after death, on account of their variations in character, site, extent, and depth.

In some cases the only perceptible lesion is congestion of the mucous membrane. This congestion is generally diffused over a space of two or three inches, involving the bulbous, membranous, and prostatic regions. It rarely involves the whole length of the urethra. Sometimes the membrane is congested in small patches from the balanic region backward.

Most frequently, owing to excessive epithelial exfoliation in the acute types and the consequent prolongation of the stage of decline, another condition is observable, and that is a granular state of the mucous membrane, designated as earuncles and carnosities by writers of the sixteenth and seventeenth centuries, and first demonstrated in the living by Désormeaux in 1864. This granular state is in reality an effort at repair. The denudation of the mucous membrane is more complete in some regions of the urethra than in others, notably in the bulbous portion of the canal, and there is a constant emigration of leucocytes, some of which become partly organized, forming the granulation tissue, while most of them are cast away as pus. Unless modified by treatment, the granular state continues indefinitely, and beneath the granulations, in the meshes of the mucous membrane, in the submucous connective tissue, and even in the spongy substance, is an exudate which in time becomes incompletely organized, sclerosed, and shriveled, constituting

stricture. The exudate and granulation tissue may be distributed in multiple patches or may encircle the urethra. Such is one of the modes of development of urethral stricture from chronic urethritis, and this development is often the work of five, ten, twenty, or thirty years. The suppleness of the urethra is impaired wherever there are granulations with an underlying exudate. The bulbous bougie and the urethroscope reveal both conditions.

Another way in which urethritis is perpetuated is when a superacute urethritis has caused acute submucous urethritis. In such a case the alteration of structure is much more profound and rapid, sclerosis, shriveling, and stricture occurring in a few months and exciting a constant muco-purulent discharge which is liable to increase in thickness and quantity after the slightest imprudence, even to the simulation of acute urethritis.

A noteworthy circumstance is the frequent development of a very mild urethritis, with slight muco-purulent discharge, from what is commonly the first stage of the acute types. This form of urethritis has some of the characters of chronic phlegmasia from the first, it is attended by phenomena similar to those of chronic urethritis consequent upon acute urethritis, and is as persistent. In these cases there are the patches of granulation tissue, the submucous exudate perhaps only in a very slight degree, and in point of fact most of the lesions found in chronic urethritis that arises from the acute types; and stricture is one of the sequelae of this form of chronic urethritis as much as it is of the ordinary chronic type.

When unchecked, chronic urethritis causes alterations of structure in the urethral mucous crypts and glands to the extent of sometimes destroying them. It is liable also to be propagated to the bulbo-urethral glands, to the prostate, to the vesico-urethral region, and even to the testicles. Long neglected, even the simplest form of chronic urethritis almost inevitably leads to stricture of the canal or to contracture of the vesical neck.

**IN THE DIAGNOSIS OF CHRONIC URETHRITIS** it should be remembered that all urethral discharges do not necessarily indicate urethritis. Thus a clear glairy discharge emanates from the urethral crypts without phlegmasic action, and likewise an extremely viscid discharge comes from the bulbo-urethral glands. A purulent discharge may come from the vesico-urethral region, from the prostate, or from the seminal vesicles. The true basis of the diagnosis of chronic urethritis rests upon a complete history of the case, gross and microscopical inspection of the discharge, and exploration of the urethra with the bulbous bougie or with the urethroscope.

If a patient, applying for treatment on account of a persistent urethral discharge, confess to one or two antecedent attacks of acute urethritis, it is fair to assume his present discharge to be the sequel of the acute urethritis, even if this attack of acute urethritis date back a few months or several years. But while this information helps, it is not sufficient to indicate the particular form and site of the existing chronic urethritis. The other aids to diagnosis, consisting in the use of instruments of precision, are essen-

tial to accuracy. The first of these aids to be used is the bulbous bougie. A No. 12 (English) bulbous bougie is ordinarily of convenient size for the purpose. This instrument is gently and slowly introduced into the urethra until the patient experiences a sense of tenderness and perhaps even of pain at a particular spot. The tender spot is generally a patch of granulation tissue covered with a layer of pus. The bulb is then carried onward about half an inch beyond the tender spot, where there may be neither tenderness nor pain, left in position for a minute, and slowly withdrawn. If the base of the bulb is coated with a whitish substance, this should at once be subjected to microscopical examination. If it proves to be pus, the granular nature of the tender spot may be considered as verified. In some cases the granulation tissue bleeds freely on the slightest provocation, and the bulb of the bougie is coated with blood. During the introduction and withdrawal of the bougie a delicate touch can discern a certain lack of suppleness of the urethra, particularly where there are several tender spots close together, or when a granular space with an underlying exudate encircles the urethral mucous membrane. This does well for urethritis anterior to the bulbo-membranous junction. If the examination is negative, all the anterior part of the urethra may be washed, and a bulbous bougie carried beyond the bulbo-membranous junction into the prostatic region and withdrawn as before. A coating of pus upon the base of the bulb will indicate the site of the granulations and source of the discharge, or, after washing the anterior urethra, the patient is asked to urinate into two separate glass vessels. If the first urine contains pus and the second is free from pus, it may be inferred that the pus has come from the membranous or prostatic region. The urethroscope, however, brings to view the granulations, their extent and their exact locality, or reveals simply a congested state of the mucous membrane, diffused or in patches.

When a stricture has already formed, there is almost always behind this stricture a granular state of the mucous membrane, which yields a more or less abundant purulent discharge. This is perhaps what has led some observers to consider that a urethral discharge is the infallible sign of stricture. In point of fact, the discharge had long preceded the stricture and was one of the phenomena of the pathic state that caused the stricture—*i. e.*, granular urethritis with an underlying exudate, the urine, partly dammed, irritating the mucous membrane immediately behind the stricture and thus perpetuating the discharge. The cure of the stricture is followed by the disappearance of the granulation tissue and of the consequent discharge.

TO TREAT CHRONIC URETHRITIS rationally and successfully it is essential to distinguish the several chronic urethral discharges, to ascertain the cause of the phlegmasia, its duration, the kind of treatment to which it may already have been subjected, and the physical condition, habits, and environment of each individual—in other words, to make a correct diagnosis. The mere gleet of clear urethral mucus requires no local treatment. It is particularly this gleet that is so excessively treated and by so many different cruel

methods. The more it is treated the worse it becomes, and finally the heroic treatment leads to an almost incurable chronic purulent discharge. Wise hygienic management and avoidance of certain factors in the causation of over-secretion of mucus, such as sexual erethism, suffice to restore the urethral glands to their normal state.

The management of sufferers from chronic urethritis is attended with many difficulties, partly owing to the moral as well as the physical condition of the patient, partly inherent to the affection itself. Their treatment should therefore be moral, general, and local. Nothing will satisfy the patient except the cessation of the discharge. To bring this about is the chief indication, so far as the view of the patient is concerned, but to the physician the indication is not only to cure the local phlegmasia which gives rise to the discharge, but to prevent the formation of stricture.

*The character of the moral management* has already been hinted at in the beginning of this conference. In addition, it may be said that the physician should gain the absolute confidence and insure the co-operation of his patient, without which all treatment would be in vain. He should dissuade him from concentrating his thoughts upon and from continuing to magnify his infirmity, and, above all, should break his habit of stripping, squeezing, and "milking" the penis to bring to view the too tardy drop, for this alone is sufficient to perpetuate the discharge which might otherwise disappear even without local treatment.

*The general treatment* is directed to the improvement of the physical condition of the patient, to place him in the most favorable hygienic condition, to combat hyperlithuria, and to strive to remove some of the causes tending to perpetuate the phlegmasia. The use of balsamics in chronic urethritis is apt to be worse than useless, for these drugs almost invariably disturb digestion even in a short time. An exception may be made in favor of the oil of gaultheria, which sometimes acts as a very effective sterilizer of the urine in chronic as well as in acute urethritis; nevertheless this agent should be used with prudence and in doses of not more than five minims thrice daily. Another valuable sterilizer of the urine is salol used in moderate doses. Alkaline mineral waters should be given sparingly and for not more than eight or ten consecutive days.

*The local treatment of chronic urethritis* varies with the site of the urethritis, the particular alteration of structure, and the complications.

In case of simple chronic urethritis, in which there are no granulations or submucous exudate, but only congestion of the mucous membrane, diffuse or in patches, particularly when this congestion is limited to the "antebulbar" region, mild astringent irrigations are indicated. It is wise, however, to keep the patient under close observation for a week or ten days, and during that time to make no local applications whatever, for the general treatment may suffice to cure the urethritis. If then the discharge persists, the urethra, for the first five or six days, should be irrigated, only once daily, with ten or twelve ounces of a solution of boric acid or biborate of sodium, five grains to the ounce. Afterward chloride of zinc should be substituted, but the zinc salt solution should not exceed half a grain to the ounce. The

quantity of fluid used for each irrigation should be about ten ounces. As a general rule, this form of chronic urethritis yields rapidly to the irrigations, and in the course of a few weeks is well.

In case of chronic cryptitis, the "antebulbar" irrigations of boric acid and afterward of zinc chloride should be made from before backward, so as to wash away from the crypts the accumulated mucus.

*Chronic urethritis with granulations* demands a somewhat different treatment, although in the beginning the irrigations with boric-acid solution should be used for several days. If the granular urethritis be "antebulbar," the best modifier that can be used is the nitrate of silver in solution of half a grain to the ounce, one grain to the ounce, and seldom increased to two grains to the ounce. The amount of fluid should not be less than six ounces, but should be used only once every four or five days.

In granular urethritis of the membranous and prostatic regions, particularly in case of coexisting chronic gonocystitis, the strength of the nitrate-of-silver solution may, with advantage, be increased to three, four, or even five grains to the ounce, and three or four ounces only need be used every four or five days. The bladder should contain a few ounces of urine in order to insure the quick decomposition of the silver salt. It is well known that when fluid is thrown slowly and without undue force through a catheter as far as the bulbo-membranous junction, it returns and escapes at the meatus, but that when the catheter is passed into the membranous region none of the fluid escapes externally, but all of it enters the bladder. Mercier pointed this out many years ago, and the experiences of other physicians have confirmed the view. Two days after each urethral irrigation a steel sound of moderate size should be cautiously introduced as far as the bladder. Too frequent catheterism or excessive dilatation only serves to defeat the objects sought to be attained. The sound should be carefully withdrawn in a minute's time, the purposes of its introduction being to make pressure upon the granulations, to slightly stretch the urethra at the seat of disease, and to restore the suppleness of the canal.

There are cases of granular urethritis that obstinately resist this treatment. These cases require direct applications to the granulation tissue, to accomplish which the use of the urethroscope becomes necessary. The granulations thus brought to view are penciled with a solution of nitrate of silver (ten, twenty, or thirty grains to the ounce) every four or five days until they disappear. Sulphate of copper and other substances have been used for the purpose, but are all inferior to the nitrate of silver.

Strong solutions are not well borne, are even mischievous, and therefore contra-indicated, in chronic urethritis anterior to the bulbo-membranous junction, but are well tolerated and effective when applied to the membranous and prostatic regions, where may be used with advantage the method of Guyon by the instillation of ten, twenty, or thirty minims of nitrate-of-silver solution (ten, twenty, or thirty grains to the ounce), to be in a minute washed into the bladder by a current of water, and repeating the process every three or four days. From Guyon's method good

results have been obtained in otherwise intractable cases, particularly those complicated with chronic prostatitis, gonocystitis, or trachelocystitis.

*Counter-irritation.*—In certain cases of chronic urethritis involving the perineal or prostatic, or both, regions of the urethra, particularly those attended with dull pain and a constant teasing sense of irritation in the parts, counter-irritation of the perinaeum by means of vesicating collodion is often of much service, and should be used every three or four days for several weeks. The vesicating collodion should be applied with a camel's-hair brush on one side of the perineal rhapshe, over a surface of half an inch by an inch and a half, and the perinaeum covered with a layer of absorbent cotton, in order that the blistered skin may speedily heal. In three days the blistering process is repeated on the opposite side of the rhapshe, and so on every three or four days until the desired effect is accomplished.

*When chronic urethritis is kept up by stenosis* of the meatus urinarius, or of any other part of the urethral canal, it can be cured only after the removal of the obstruction to urination, in the first case by incision, in the second case by dilatation, divulsion, or incision, according to the character and particular site of the stricture.

*In chronic urethritis due to urethral tuberculosis* no treatment other than the palliative is of any avail. The discharge increases in quantity from day to day, in it swarm the characteristic tubercle bacilli, and the patient soon succumbs to the inroads of general tuberculosis. A specimen exhibited showed tuberculosis extending from the meatus urinarius to the bulbo-urethral glands, spermatic canals, seminal vesicles, prostate, bladder, peritonaeum, and right ureter and kidney. The left kidney had undergone compensatory enlargement and was not tuberculous. Both testicles had been extirpated, on account of tuberculosis, six months before the death of the patient. The specimen was a particularly good illustration of ascending tuberculosis of the urinary apparatus. There had been for several weeks a thick urethral discharge, in which great numbers of tubercle bacilli were detected. Several other specimens were exhibited to illustrate descending tuberculosis of the urinary apparatus. The disease, having begun in the lungs, secondarily affected the kidneys, descended to the bladder and urethra, and caused an obstinate purulent discharge.

**Does Ether assist Digestion?**—"The effect of ether on the digestive processes in healthy subjects has been recently investigated," says the *Lancet*, "by Dr. Gurieff, who gave thirty drops of sulphuric ether to six healthy persons during dinner, which consisted of about half a pint of soup, four ounces of meat, and six ounces of bread. It was found that the ether had the effect of stimulating the action of the gastric glands, increasing the free hydrochloric acid in the gastric juice, and causing the peristaltic movements of the stomach, together with its power of absorption, to increase; thus on the whole exercising a favorable effect upon the gastric digestion. The same result was obtained when the ether was administered by means of hypodermic injections. It would appear, therefore, that the effects must be ascribed to a general rather than to any merely local action on the mucous membrane of the stomach. Dr. Gurieff is disposed to think that there is a stimulation of the cephalic centers. This view is partly based on the observations of other Russian observers—Bekhtereff and Miloslevski, and Pavloff and Shumova-Simanovskaya—on the dependence of the gastric functions upon the central nervous system."

## SKIN-GRAFTING BY THE THIERSCH METHOD FOR CICATRICIAL DEFORMITY OF THE EYELIDS.

By J. H. WOODWARD, M. D.,

BURLINGTON, VT.,

PROFESSOR OF OPHTHALMOLOGY IN THE UNIVERSITY OF VERMONT.

CASE I. *Cicatricial Lagophthalmus*.—In November, 1890, John L., a laboring man, about thirty-five years of age, consulted me at the Mary Fletcher Hospital for relief from the results of an injury received several years earlier. He had been kicked by a horse, and the resulting lacerated wound of the left upper eyelid had healed with deformity, owing to which he was not able to close his eye, even by forced muscular effort.

I found an irregular scar extending from the middle of the free border of the lid in a vertical direction nearly to the eyebrow, and involving the skin and muscular tissue. The ciliary margin of the lid was deeply notched at the scar and the eye remained permanently open. I ordered the region of the left eye to be thoroughly cleansed with soap and water and disinfected with  $\frac{1}{5000}$  solution of the bichloride of mercury, the conjunctival sac to be irrigated with a saturated solution of boric acid, and the eye then to be covered with an antiseptic dressing. His left shoulder, from which I purposed to take the graft, was cleansed and disinfected and dressed in a similar manner. These measures were repeated three times in the twenty-four hours immediately preceding the operation.

Just prior to the administration of the anæsthetic all instruments, sponges, and dressings to be used in the case were sterilized by superheated steam, and a one-per-cent. solution of common salt was filtered and sterilized for use during the operation for irrigating the wound and for moistening the dressing after it. Ether was then administered, and the region of the operation was again disinfected with the bichloride solution and finally thoroughly washed with the saline solution. I then made an incision nearly the entire length of the upper eyelid at right angles to the scar and nearly one centimetre from the ciliary margin, through the skin, and into the muscular tissue until I had penetrated deeper than the cicatrix. The upper and lower lips of the wound were dissected up until the free border of the lid had returned to its normal curve, which is convex below when the eyes are closed. The upper and lower lids were then bound together with a single median suture. Having checked all oozing from the wound, I shaved from the previously disinfected shoulder a graft about three centimetres long, one centimetre broad, and two millimetres thick. This fitted the wound in the eyelid, to which it was immediately transferred and gently pressed into its bed. Both wound and graft had been thoroughly wetted with the sterilized one-per-cent. saline solution. The dressing was protective sterilized gauze moistened with the saline solution, and a bandage. Every two hours, day and night, the dressing was moistened with the saline solution.

On the second day the case was redressed with aseptic precautions, and the graft was found in good condition. There was some muco-purulent discharge from the conjunctiva. Redressed as before. The moist dressing was continued four or five days, and at the end of a week the graft had united firmly with the eyelid; only a very narrow strip of the outer end of it had perished. The result was complete relief of the lagophthalmus. The grafted tissue so closely resembled the surrounding parts that one could distinguish it only by closely scrutinizing the eyelid.

CASE II. *Cicatricial Ectropium*.—George P., aged twenty-two, an Adirondaek guide, consulted me in October, 1891, for deformity of his right lower eyelid, which was caused by a dog-

bite when he was four years old. The right lower lid was everted and drawn downward by the cicatrix. The exposed conjunctiva was inflamed and thickened by the prolonged exposure. The inferior punctum lacrymale was drawn away from the eyeball, and the resulting epiphora was a constant annoyance to him. The cicatrix causing the deformity was irregular; its chief traction was expended on a point about a centimetre to the inner side of the median line of the lid.

The preliminary treatment, the aseptic management, and the operation in this case were similar to those described above. In this instance, however, the wound being larger and more irregular, I imbedded two grafts in it instead of one, for I did not succeed in cutting a single graft of suitable shape and size to fill the wound. The dressing was similar to that in the first case. On the second day I redressed the case, and found that the inner graft had perished. It was adherent to the protective and came away with the dressing, thus exposing one third of the wound. A profuse muco-purulent discharge had been poured out by the conjunctiva. The stitches uniting the upper and lower lids had cut through and were removed. Redressed as before. Two days later the wound was doing well. Numerous small grafts were transplanted from the forearm to the bed of the dead graft, which was thus completely covered. Nearly all these small grafts lived. In a week the wound was healed, the line of the ciliary margin of the lower lid was almost perfectly restored to its normal curve, the punctum was in normal contact with the eyeball, and it was not easy to distinguish the grafts from the normal integument.

The advantages of this method of handling deformities of the eyelids are too evident to require discussion. It is not easy to do an aseptic operation in the region of the eye; it is perhaps impossible to secure perfect asepsis there. Nevertheless, a sufficient approximation to the aseptic state is attainable to warrant a successful termination of the treatment. One of the features highly commendatory of this surgical procedure in deformities about the face is that the traces of the operation are practically invisible.

---

**Sensory and Vaso-motor Disturbance in Facial Paralysis.**—"Dr. Frankl Bochwitz, in an investigation into the conditions present in twenty cases of facial paralysis, found that in three there were disturbances of sensation and of the vaso-motor functions, in five of sensory functions only, and in two of vaso-motor only. The sensibility was only affected to a very slight degree, and sometimes the mucous membrane on the tongue and inside of the cheek was affected, and sometimes it was not. Occasionally also taste was affected. These sensory phenomena disappeared much earlier than the paralysis, but in one case in which the paralysis persisted there was diminished sensibility even after several years. The conclusion sought to be drawn from these facts is that the facial nerve in man contains some sensory and vaso-motor fibers; but of course it would first have to be shown that the fibers of the fifth nerve had not also suffered when the facial nerve became affected."—*Lancet*.

**A Gastrolith in Man.**—"Dr. Kooyker has reported in the *Zeitschrift für klinische Medizin* another case of gastric calculus—a condition which, though common enough in animals, is so rare in man that so far only seven cases have been reported. Dr. Kooyker's case was that of a man fifty-two years old, in whose lifetime it had been impossible to make a positive diagnosis, though some neoplasm of the stomach was suspected. The patient died from exhaustion. At the post-mortem examination a concretion was found in the stomach, almost entirely filling its cavity, which weighed eight hundred and eighty-five grammes and was eighteen centimetres in length. The microscopic examination resulted in finding starch, vegetable cells, chlorophyll, and vascular tufts, while hair and other animal elements were entirely absent."—*Lancet*.

THE  
NEW YORK MEDICAL JOURNAL,

*A Weekly Review of Medicine.*

Published by  
D. APPLETON & Co.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, FEBRUARY 13, 1892.

AN UNWARRANTABLE ATTEMPT TO SECURE SPECIAL  
LEGISLATION.

A COMMITTEE of the Senate of the State of New York has lately given its attention to a bill granting to such medical students as entered upon their college courses after the new medical law went into effect, but during the same year, exemption from the requirement of passing the State examination. We are informed that a thousand students have joined in the ignoble undertaking of getting this bill passed by the Legislature. That number is a disgracefully large proportion of all the medical students in the State, and a still larger proportion of those who may be supposed to be directly interested in the matter—that is, of those who were matriculated within the time specified.

The senatorial committee seems to be unaccountably lenient toward the promoters of this extraordinary bill, for we understand that one of its members has asked a well-known physician if he did not suppose that the 'students' motive was the outgrowth of their straitened circumstances, of their inability to pay the State examination fee. Such guilelessness in the Legislative mind is indeed refreshing. Nobody in the medical profession can have much doubt about their motive; it is simply that they find themselves confronted with a fence that they think they can not leap over, and they are calling on the Legislature to slip them under the rails.

There is, of course, no reason worth listening to why these particular students should be exempted from a just legal requirement. If they are exempted, it is difficult to imagine on what grounds the Legislature can decline to accord the same measure of favor to the following year's crop of students, and so on indefinitely, thus practically nullifying a most wholesome enactment. The pending bill is pernicious in the extreme, and we hope that it will never get beyond the committee.

THE ETIOLOGY OF CHANCROID.

WHEN, nearly forty years ago, Bassereau and Clerc pointed out clearly the distinction between the chancre and the chancreoid, great efforts were made to establish the theory of the existence of two distinct viruses, the syphilitic and the chancreoid. This idea of dualism was so simple and striking that it gained quite general acceptance, and we find eminent authors in Europe and in this country teaching the doctrine that no amount of sexual excess, no degree of uncleanness, no irritation, traumatic or chemical, in short, nothing, can produce chancreoids except chancreoids and chancreoidal buboes; or, as Fournier has put it, "if all the chancreoid

patients in the world would avoid contact with others until they got well, the disease would cease from off the face of the earth." There were those, however, who did not blindly accept this doctrine, and who could see nothing mysterious or specific in the chancreoid. Among this number were Dr. Bunnstead and Dr. Taylor, of New York, whose investigations, both experimental and clinical, proved beyond a doubt that ulcers having all the features and peculiarities of chancreoid could be produced by many different varieties of pus, the chief essential being the activity of the ulcerative process in the sore from which the pus was taken. It was natural to expect that modern bacteriological research would throw much light upon this subject, but studies in this department have been disappointing, and have only succeeded in establishing the fact that the chancreoid is produced by pus rich in pyogenic microbes.

It is well known that most chancreoids are contracted during sexual intercourse, one of the persons concerned being already affected with this form of ulceration; but it is not so generally known that chancreoids may be found on the penis of a man, and yet the woman with whom he cohabited be free from these lesions. Such instances are by no means rare, as may be seen by reference to a recent article on this subject by Dr. R. W. Taylor in the *Medical News* for December 5, 1891. This author cites a case in which a healthy young man, presenting no evidences of syphilis or gonorrhœa, came to him with seven true chancreoids in the balano-preputial sulcus. He was positive that the woman with whom he had cohabited was free from any such trouble, and an examination of this woman showed nothing but a deep and highly ulcerated fissure of the os uteri, surrounded by an area of intense hyperæmia. Brownish, gelatinous pus escaped profusely from this ulceration. On inquiry, it was learned that since this woman had had a child, seven years before, she had had leucorrhœa most of the time, and that four weeks before this examination she had been taken sick with what was called peritonitis. She remained three weeks in bed, and then, on getting up, indulged freely in sexual intercourse with this man, at the same time drinking large quantities of wine. The result was that he became affected with chancreoids, and she suffered greatly from pelvic pain.

Here, then, is a case in which, in consequence of an acute attack of peritonitis, together with sexual excess, a discharge from a subacute inflammation becomes converted into a more active form of pus. The important clinical fact brought out by this case is in direct accord with the results of inoculation experiments which have been made by various observers with pus from acne, ecthyma, impetigo, scabies, etc., in which lesions were produced in no way distinguishable from chancreoids. The lesson taught by the case should be widely known, for it is easy to see how a physician, ignorant of this fact, might cruelly wrong innocent women.

Syphilitic women who are entirely free from specific lesions of the genitals often have a purulent vaginal secretion which is rich in pyogenic microbes, and which is capable of producing chancreoids in men; while, on the other hand, it is not unusual for men to cohabit with impunity with women having an old

and extinct syphilis and chronic chaneroids. There are not a few medical men who think that, because chaneroid is classed as a venereal disease, it must of necessity originate in sexual contact, yet in many instances this supposition is not correct, for, says Dr. Taylor, chaneroids may originate in some subjects *de novo*. In other words, chaneroids may develop in men who have had no sexual intercourse whatever, as a result of some diathetic condition or some contamination of herpetic vesicles, chafes, abrasions, or fissures.

In the article referred to Dr. Taylor cites two striking examples of this class of chaneroids. In the first case, a man, twenty-nine years of age, of plethoric habit and seemingly in robust health, presented himself with a typical chaneroid of the inner side of the prepuce. He insisted that he had not had any intercourse for a month, and said that under like circumstances he had had precisely similar ulcers, which had been pronounced by eminent surgeons and syphilographers in America and Europe as undoubtedly chaneroids. The patient was kept under observation for a number of years, and it became evident that he was a victim of a persistently recurring herpes progenitalis, which at times would heal promptly, and at other times would be transformed into unhealthy ulcers, which could not be distinguished from classical chaneroids. The second case was even more remarkable. A man, thirty years old, thin and rather pale, had suffered for about ten years with frequent attacks of herpes progenitalis. He had had severe attacks of gonorrhœa when twenty-four and twenty-six years of age. He had never had syphilis. These attacks of herpes began with a smarting, burning pain; the vesicles were situated on the skin of the penis, on the inner surface of the prepuce, or near the frenum and meatus urinarius. In the early attacks the vesicles healed under simple treatment in about a week, but as years went on he noticed that sometimes the vesicles assumed an unhealthy, ulcerated appearance and were very rebellious to treatment. Being a thoughtful and observant man, he soon convinced himself that these attacks of herpes were never the result of coitus, as sometimes the herpes would appear a few days after coitus, and again it would appear after many weeks of abstinence. Before he came under the author's observation, in 1886, a crop of herpetic vesicles suddenly appeared in the left fossa of the frenum, notwithstanding he had not had sexual intercourse for three months. He had learned to be scrupulously clean about his genitals, but, notwithstanding this, the crop of vesicles rapidly developed into a larger ulcer, which a surgeon pronounced to be an unmistakable chaneroid and stoutly maintained could only have been contracted *in coitu*. After two weeks of careful treatment, chiefly with iodoform, the ulcer healed, but not before two virulent buboes had appeared. Following these buboes, a deep sloughing ulcer formed in the left groin and a similar ulcer on the thigh, just below the groin. It was at this time that he presented himself to Dr. Taylor for treatment. The ulcers were thoroughly irrigated with a five-per-cent. carbolic-acid solution, the parts were carefully dried, and the morbid surface was dusted with iodoform and covered with gauze and a bandage. On the anterior sur-

face of the thigh there were three little ulcers, in all respects like chaneroids, and several hair follicles were the seat of a deep hyperæmia. According to the patient's statement, the lesions upon the thigh were caused by a purulent discharge from the buboes, as he had been unable to dress the ulcers properly while traveling. These ulcers were treated in the same way as the others, and all the lesions were healed in about three weeks. In this case the possibility of a lymphatic infection from a lesion of the foot, leg, or buttocks was carefully excluded, and infection from sexual intercourse was entirely out of the question. During the following years recurring attacks of herpes were experienced, in some of which the vesicles were converted into destructive ulcers, and on two occasions, as the result of a most rigid antiseptic treatment at the very beginning, the vesicles were dried up and prompt healing was secured. Again, in 1890, after abstinence from coitus for four months, he was attacked with preputial herpes near the right of the frenum. The vesicles developed into a typical chaneroidal ulcer, and the ganglia in the right groin became swollen and painful. The ulcer was treated with iodoform, and cold was applied to the groin. The chaneroid healed, but the ganglia went on to suppuration, and after free incision a deeply ulcerated surface was left, which presented the typical appearance of a virulent bubo.

It is important not to forget that simple inflammatory lesions of the genitals in syphilitics are often converted into typical chaneroids or septic ulcers, undoubtedly as the result of contamination with pyogenic microbes from some unknown source. Pus taken from these chaneroids is capable of producing, on inoculation, similar lesions for many generations. Clinical observations seem to show that chaneroids derived from the pus of patients in whom the syphilitic diathesis is quite active are commonly more active than those caused by the various forms of simple pus. It is also well to remember that lesions of continuity occurring about the genitals of old syphilitics, both men and women, are prone to assume the features and characteristics of chaneroids.

The tissues of the genitals of syphilitic women are also liable to the development of chaneroids upon all lesions of continuity. Thus, in the case of a young woman who had been syphilitic for a year, and, in consequence of a vulvar pruritus, had produced an excoriation of the right nymphæ by scratching, a large and typical chaneroid developed on this raw surface, and a virulent bubo appeared a few days later. She had absolutely refrained from coitus for a month previous to this trouble.

It thus appears that what we call chaneroid is the product of many varieties of pus, derived from non-syphilitic and from syphilitic subjects, and that it is, therefore, in all cases, a septic ulcer and in many instances simply an active form of wound infection. From this it follows that Fournier's dictum, already quoted, is utterly false, and that so long as pyogenic microbes and tissue predisposition exist, chaneroids will be found upon the mucous membranes and integument of the human race.

## MINOR PARAGRAPHS.

## THE TOXIC ACTION OF IMPURE CHLOROFORM.

It has been an axiom for years that in the administration of chloroform for anaesthesia the purified drug only should be employed. This has been founded in part upon observation and in part upon a knowledge of the irritative effects of some of the impurities in commercial chloroform. Professor Pietet's recent method of refining chloroform, mentioned in the *Journal* for December 12th, gives a very pure chloroform and an impure residue. Dr. René du Bois-Reymond has recently published in the *British Medical Journal* the results of his experiments upon the physiological action of the residue as compared with that of the purified drug, cardiographic tracings being made of the hearts of frogs placed under covered dishes with both liquids, and manometric and respiratory tracings being made from rabbits inhaling the drugs through a tracheal cannula.

These experiments corroborated those already made on the action of chloroform in general, but, on comparing the pure with the impure drug, no difference was found in the shape of the pulse waves or in the frequency of respiration. With the residue, at the close of the experiments, the pulse rate was higher than with pure chloroform; and when respiration stopped, the blood pressure was higher after inhaling the pure than the impure drug. Furthermore, the latter caused stoppage of respiration much more quickly than the former. Pure chloroform is much more volatile than the impure, and the purer the drug the less the quantity required for anaesthesia and the less risk of that respiratory failure which the Hyderabad Commission concluded was the cause of death in chloroform administration.

## WARMED ETHER AS AN ANAESTHETIC.

From the *British Medical Journal* for December 19th we learn that a surgeon of Barcelona, Spain, has devised a plan for administering ether in a warmed condition. Dr. Giné y Paragás performed an operation in October, 1891, for osteoma of the fibula, on a woman in the Hospital de la Santa Cruz, of the city above named. This operation, which was reported in the *Independencia Médica*, was the first one of magnitude to be carried through under the new anaesthetic process. The ether was administered by Dr. Diaz de Liano, the designer of the apparatus. The temperature at which the ether was kept was 87° F. Insensibility was quickly induced and was maintained for fifty-five minutes without accident. The ether was kept at 87° until near the close, when it fell to 85°. The apparatus, which has been called an "electro-thermo-etherizer" by its designer, has since been used satisfactorily. In one case the administration was prolonged for two hours and a half without ill effect. The new method, it is maintained, will do away with some of the disadvantages both of chloroform and of cold ether. A full description of the apparatus is promised to be published at an early date.

## THE KINGS COUNTY INSANE ASYLUM.

The Commissioners of Charities of Kings County have voted to make a change in the supervision of the asylums at Flatbush and St. Johnland. Dr. John A. Arnold, of the Flatbush Asylum, will be temporarily superseded by Dr. Walter Fleming, who is at present one of Dr. Arnold's assistants, and who will in turn be replaced by a general medical superintendent to be appointed in accordance with the rules governing the State Commission. The new appointee will be given general oversight of all the hospitals for the insane poor. This action probably terminates Dr. Arnold's long and useful career in the adjoining

county of Kings. We wish him a larger and more congenial field, with a greater freedom from political interference and annoyance.

## LARGE VITAL CAPACITY IN A NEZ PERCÉ INDIAN.

On the occasion of the recent visit to the Indian School at Carlisle, Pennsylvania, of a party of Nez Percés, the physician of the school made a physical examination of several of the visitors. One of them, who was five feet and an inch in height, and weighed one hundred and sixty pounds, was the possessor of a clear chest expansion of five inches. When we remember that a free expansibility of four inches is seldom possessed, except as the result of special respiratory training, the lung capacity of this red man will be recognized as something remarkable.

## ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending February 9, 1892:

DISEASES.	Week ending Feb. 2.		Week ending Feb. 9.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever . . . . .	11	2	9	7
Scarlet fever . . . . .	192	19	210	25
Cerebro-spinal meningitis . . . . .	2	1	2	1
Measles . . . . .	137	12	132	13
Diphtheria . . . . .	87	30	122	23
Small-pox . . . . .	5	0	11	2
Erysipelas . . . . .	0	0	0	0
Varicella . . . . .	0	0	0	0
Pertussis . . . . .	0	0	0	0
Leprosy . . . . .	0	0	0	0

**The Verein deutscher Aerzte von Brooklyn.**—The special order for the meeting of Friday evening, the 12th inst., was a paper on Post-partum Haemorrhage, by Dr. A. Ritter.

**The Hospital for the Insane at Asbury, Iowa.**—Dr. J. J. Brownson, of Dubuque, has been appointed physician to the hospital.

**The Conemaugh Valley Memorial Hospital** was opened at Johnstown, Pa., on Thursday, the 4th inst., with appropriate inaugural ceremonies. Among the addresses was one by Dr. George W. Wagoner.

**The Death of Dr. David Fleischman, of Albany,** occurred on January 30th. The deceased was a graduate of the Albany Medical College, of the class of 1881, and subsequently studied laryngology and rhinology at the New York Post-graduate Medical School. He had devoted himself to these branches since 1883, and was highly esteemed by the profession and the community.

**The Death of Professor von Bruecke.**—The *Wiener klinische Wochenschrift* announces that Dr. Ernst W. Ritter von Brücke, emeritus professor of physiology in the University of Vienna, died on the 7th of January, at the age of seventy-two.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 24 to February 6, 1892:*

BURTON, HENRY G., Captain and Assistant Surgeon, having been found incapacitated for active service by an Army Retiring Board, is granted leave of absence until further orders, on account of disability.

The order relating to Captain AARON H. APPEL and First Lieutenant JULIAN M. CABELL, Assistant Surgeons, is suspended until further orders.

WRIGHT, JOSEPH P., Lieutenant-Colonel and Surgeon, is relieved from duty as attending surgeon at the Military Prison, Fort Leavenworth, Kansas, and will repair to San Francisco Cal., and assume the duties of Acting Assistant Medical Purveyor, taking charge of the medical purveying depot at that place, and relieving Lieutenant-Colonel

GEORGE M. STERNBERG, Surgeon, who, upon being relieved, will proceed to Governor's Island, New York, and report in person to the commanding general, Department of the East, for duty as attending surgeon and examiner of recruits in New York city.

SNYDER, HENRY D., First Lieutenant and Assistant Surgeon, now temporarily serving at Fort Reno, Oklahoma Territory, is assigned to duty at that post.

DUNLOP, SAMUEL R., First Lieutenant and Assistant Surgeon, is relieved from duty at Fort Sill, Oklahoma Territory, and assigned to duty at Fort Supply, Indian Territory, where he is now temporarily serving.

BROOKE, JOHN, Major and Surgeon, is granted leave of absence for twenty-eight days.

APPEL, AARON H., Captain and Assistant Surgeon, is granted leave of absence for twenty-three days.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the three weeks ending February 6, 1892:*

FARWELL, W. G., Surgeon. Detached from the Naval Hospital, Norfolk, and to wait orders.

DRAKE, N. H., Passed Assistant Surgeon. Ordered to the Naval Hospital, Chelsea, Mass.

PICKRELL, GEORGE McC., Passed Assistant Surgeon. Detached from the Naval Hospital, Chelsea, and ordered to the Naval Hospital, Norfolk.

MCCORMICK, A. M. D., Passed Assistant Surgeon. Detached from the Receiving-ship Minnesota and ordered to the U. S. Steamer Charleston.

BARBER, GEORGE H., Assistant Surgeon. Detached from the U. S. Steamer Charleston and ordered to the Receiving-ship Minnesota.

CABELL, A. G., Passed Assistant Surgeon. Detached from the U. S. Steamer Newark and ordered to the U. S. Steamer Kearsarge.

STOUGHTON, JAMES, Assistant Surgeon. Detached from the Naval Hospital, Norfolk, Va., and ordered to the Training-ship Portsmouth.

GUEST, M. S., Assistant Surgeon. Detached from the Navy Yard, Norfolk, Va., and ordered to the Naval Hospital, Norfolk, Va.

NEILSON, J. L., Surgeon. Detached from Training-ship Portsmouth, and granted two months' leave of absence.

**Marine-Hospital Service.**—*Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the four weeks ending January 16, 1892:*

IRWIN, FAIRFAX, Surgeon. Granted leave of absence for seven days. January 13, 1892.

CARTER, H. R., Passed Assistant Surgeon. To proceed to Cincinnati, Ohio, and assume command of the service. January 8, 1892.

BROOKS, S. D., Passed Assistant Surgeon. To inspect unseaworthy property at Marine Hospital, Detroit, Michigan. December 23, 1891.

WILLIAMS, L. L., Passed Assistant Surgeon. Granted leave of absence for twenty days. January 12 and 13, 1892.

PETTUS, W. J., Passed Assistant Surgeon. To proceed to Buffalo, N. Y., and assume command of the service. December 21, 1891.

MAGRUDER, G. M., Passed Assistant Surgeon. Relieved from duty at Washington, D. C.; ordered to Marine Hospital, New Orleans, La. January 8, 1892.

PERRY, T. B., Passed Assistant Surgeon. To proceed to Cape Charles Quarantine for temporary duty. January 13, 1892.

#### Death.

LONG, W. H., Surgeon. Died at Cincinnati, Ohio, January 5, 1892.

#### Society Meetings for the Coming Week:

MONDAY, February 15th: New York County Medical Association; New York Academy of Medicine (Section in Ophthalmology and Otolaryngology); Hartford, Conn., Medical Society; Chicago Medical Society.

TUESDAY, February 16th: New York Academy of Medicine (Section in General Medicine); New York Obstetrical Society (private); Ogdensburg Medical Association; Medical Societies of the Counties of Kings and Westchester (White Plains), N. Y.; Baltimore Medical Association.

WEDNESDAY, February 17th: Northwestern Medical and Surgical Society of New York (private); Harlem Medical Association of the City of New York; Medico-legal Society; New York Academy of Medi-

cine (Section in Public Health and Hygiene); New Jersey Academy of Medicine (Newark).

THURSDAY, February 18th: New York Academy of Medicine; Brooklyn Surgical Society; New Bedford, Mass., Society for Medical Improvement (private).

FRIDAY, February 19th: New York Academy of Medicine (Section in Orthopædic Surgery); Baltimore Clinical Society; Chicago Gynecological Society.

SATURDAY, February 20th: Clinical Society of the New York Post-graduate Medical School and Hospital.

#### Answers to Correspondents:

No. 371.—We think that pneumonia can not be said to be caused by the use of alcohol, but it is of frequent occurrence in the subjects of alcoholism, and, like most diseases, is more fatal in them than in others. We are not aware that pneumonia in alcoholic subjects has features distinctive enough to warrant the term alcoholic pneumonia.

## Proceedings of Societies.

### MEDICAL SOCIETY OF THE STATE OF NEW YORK.

*Eighty-sixth Annual Meeting, held at Albany on Tuesday, Wednesday, and Thursday, February 2, 3, and 4, 1892.*

The President, Dr. A. WALTER SCUTER, of Herkimer, in the Chair.

**A Pathological Review of Diphtheria, with Special Reference to a New Method of Treatment, based upon Three Years' Practical Experience,** was the title of a paper by Dr. F. E. MARTINDALE, of Port Richmond. The history and ætiology of the disease were discussed at some length, and the fatality so common in rural districts was ascribed to imperfect ventilation in the houses, to dampness, and to the presence of an abundance of bacilli, which probably originated in vegetables stored in cellars. The author's method of treatment consisted in raising the temperature of the sick-room to 104° F., and saturating the atmosphere with the vapor of tar and turpentine, which were mixed in equal portions and constantly vaporized by the action of heat during the progress of the disease. Twenty-three patients had been treated in this way, and all but one had recovered, and that one had not been seen until the disease was beyond cure.

Dr. S. BARUCH, of New York, approved of the method which had been advocated, but did not look upon it as a new one. It had been used by others, and he had used it himself eight or ten years before.

**Asepsis and Antiseptics in Obstetrical Practice.**—Dr. GEORGE SEYMOUR, of Utica, read a paper in which he advocated the precautions which modern midwifery insisted upon, including the free use of carbolic acid, sublimate, and creolin.

Dr. ANDREW F. CURRIER, of New York, believed that the essence of successful treatment in obstetric practice was cleanliness. Antiseptics were not indicated in normal cases. Unusual precautions, aside from cleanliness, though possible in hospitals, were often impossible or impracticable in the dwellings of the poor.

**The Treatment of Endometritis.**—Dr. RALPH WALDO, of New York, read a paper thus entitled. This disease, he said, had many phases, and was in many cases most difficult to cure. One of the most useful means of treatment was drainage. The idea of drainage of the uterus was not new. The words of Sims were quoted, describing the value of this means of treatment in terms which would apply to methods in vogue at the present

time. Intra-uterine douches of hot water were also an efficient means of treatment, which were to be used in conjunction with suitable means for drainage, whether such means were gauze, glass, or rubber. The application of escharotics to the interior of the uterus was attended with no little danger. Stenosis and cicatrization after such treatment were often a source of much trouble.

Dr. CURRIER believed that drainage was one of the most important means of treatment in the hands of the gynecologist. He also insisted upon the great importance of the intra-uterine tampon in the treatment of endometritis, as well as in numerous other pathological conditions of the uterus, not only furnishing, as it did, a most efficient means of drainage, but also serving as a stimulant to the uterine muscular tissue.

Dr. W. B. CHASE, of Brooklyn, agreed with the reader of the paper in reference to the dangerous character of escharotics in the treatment of endometritis. He was a firm believer in the curette and in dilatation as suitable means of treatment.

Dr. HAYD, of Buffalo, referred to the danger of exciting tubal disease by the use of violent means of treatment. He agreed with the previous speakers in regard to the danger of escharotics and the essential value of drainage, especially when the gauze tampon was used.

Dr. SEYMOUR believed that in numerous instances an oophoritis or salpingitis was caused by the freedom with which the uterus was invaded in the treatment of endometritis. He was disposed to attach great importance to the use of tonics, suitable diet, and exercise as means of treatment, believing that the endometritis was frequently only a manifestation of a depraved general condition.

Dr. R. B. TALBOT, of New York, thought that dilatation was a valuable measure if properly applied. He preferred gradual dilatation with bougies and sounds to the use of powerful expanding instruments. He had seen no accidents resulting from dilatation, as he was in the habit of using it.

**Open Incision for Talipes Varo-equinus.**—Dr. A. M. PHELPS, of New York, read a paper thus entitled. This operation had been first performed by him in 1879, and he had been able to present to the society the histories and photographs of some of his earliest cases. The cures effected by his method had been permanent, and the children who had been operated upon had grown up with useful and shapely limbs. He was the more pleased to make this report inasmuch as there had been much skepticism as to the value of his operation. All the soft parts were divided in his incision, which began at the internal malleolus and extended a third the distance across the foot. Osteotomy should not be done in these cases, as a primary operation for a permanent cure was less likely to result, and even a fatal result had occurred in a few cases. The equinus was to be overcome by subcutaneous division of the tendo Achillis, and this should be done prior to the incision for the relief of the varus. A series of 161 operations upon 93 patients was reported, in which there had been but ten relapses. In only 17 cases had he found it necessary to perform linear osteotomy.

Dr. WILLY MEYER, of New York, narrated cases which had come under his observation. The treatment of these cases should be begun almost at birth. Some of them could be corrected by pressure and traction, but, if such measures failed, Phelps's operation was indicated.

Dr. HERMAN MYNTER, of Buffalo, believed that operative measures frequently became necessary in consequence of the carelessness of mothers in following out the directions of the surgeon when milder measures had been resorted to. Such an operation as was under discussion frequently obviated the necessity of amputation.

Dr. PHELPS said that a failure might result if the incision was not extensive enough, and he believed that surgeons sometimes erred in this particular. His formula was to make the incision before performing a bone operation, and to avoid the latter if possible.

**Mineral Springs in the Treatment of Disease.**—Dr. CHARLES C. RANSOM, of New York, read a paper which was a plea for the more careful study and classification of the mineral springs of this country, and in particular a study of the sulphur waters of Richfield Springs, N. Y., and their application to the relief of various constitutional disorders.

**Amputation of the Vaginal Portion of the Cervix Uteri in Cases of Suspected Carcinoma.**—Dr. CURRIER read a paper thus entitled. (To be published.)

**The Mental Derangements observed in Multiple Neuritis, especially that of Alcoholic Origin.**—Dr. E. D. FISHER, of New York, read a paper thus entitled. The symptoms of this disease, as given by Starr, were briefly described. Especially important as a symptom was the loss of knowledge of time and place during the illness. The patient was conscious of experience which occurred until his illness began, but from that period until his recovery all was a blank to him. The disturbance of function was most manifest in the upper extremities, and was derived from lesions of the association fibers of the brain. The disease might continue for months, improvement in the peripheral nerves and mental condition taking place, and recovery resulting eventually. The disease occurred not only in those who had long been addicted to alcoholic excesses, but in moderate drinkers as well.

**Two Successful Cases of the Conservative Cæsarean Section.**—Dr. CHARLES JEWETT, of Brooklyn, reported the following cases: **CASE I.**—An English woman, thirty-two years of age, four feet six inches in height, was in fair health with the exception of a chronic nephritis. The pelvis was kyphotic, and the inlet slightly contracted; the outlet two inches and three quarters in the pubo-occygeal, and two inches and a quarter in the bisischiatic diameter. She was admitted into the Long Island College Hospital after being several hours in labor. The os externum was dilated to the size of a half-dollar and the membranes had ruptured. The operation was done on December 2d. The pulse was 90. A large, thin-walled rubber tube was used as a cervical constrictor. The placental seat was under the uterine incision. A hand was passed over the left edge of the placenta and through the membranes. The head was extracted with difficulty and only after relaxing the grasp of the constrictor. The umbilical cord was clamped at two points with catch-forceps and cut between them. The child was alive and respiration was promptly established. There was no evagination of the uterus. The placenta and membranes were separated by the hand, and the uterine cavity was left undisturbed. The uterus was closed with twelve deep silk sutures and a symperitoneal suture of catgut. Hardly any handling and no special cleansing of the peritonæum took place. The abdomen was closed with ten silk sutures. The loss of blood was no greater than in ordinary labor. The tonicity of the uterine muscles was apparently unimpaired by the cervical ligature. A good recovery was made, with no sign of sepsis. The abdominal sutures were removed on the tenth day. Uterine involution was somewhat tardy.

**CASE II.**—A German immigrant, twenty years of age, had for a long time been subject to hysterical paroxysms, occasionally ending in convulsions and semi-coma. She was in bad condition from inanition, and was the subject of a slight bronchopneumonia at the time of the operation and also of syphilis in the second stage. A most remarkable feature of this case was the temperature record. The thermometer several times regis-

tered 107° F., and once 110°. At the beginning of the operation her temperature was 108.6°. This woman was of slender figure and four feet six inches and a half in height, and her pelvis was extremely flattened. The true conjugate was two inches and a half, and the pubo-eccegeal and bischial diameters were each two inches and a quarter. She fell into labor shortly after the sixth month of gestation. The operation was done about ten hours after the first pains. The waters had drained away, but the cervix would barely admit the examining finger. The section was complicated with troublesome protrusion of intestines, owing to tympanites. There was nearly a complete escape of the liquor amnii, with placenta prævia Cæsareana. A large, thin-walled rubber tube was used as a uterine ligature as in the previous case. The placenta was separated as before. The child was alive and breathing, but not viable. The uterus was lifted out of the abdomen. The membranes were separated with difficulty. The uterus was closed with ten deep sutures in fourteen minutes from the beginning of the operation. The decidua was not included in the sutures. Symperitoneal sutures of silk were used. No flushing and little cleansing of the peritonæum were employed. The abdominal incision was closed with ten silk sutures. The temperature at the close of the operation was 98.6°, and the pulse 90, lower than at the beginning. There was some abdominal distention on the second day, which was promptly and permanently relieved by free evacuations of the bowels with salines. The temperature soon resumed its customary oscillations, but there was no bad symptom attributable to the abdominal section and the patient made a satisfactory recovery.

The writer mentioned as the most important points in the technique of Cæsarean section asepsis, the secure closure of the uterine wound by the typical Säger suture with silk, and the avoidance of all scrubbing and use of antiseptics of any kind in the aseptic uterine cavity and irrigation or much sponging of the peritonæum. The resort to saline cathartics soon after the first expulsion of flatus he considered a valuable measure. The best time for operation, in his opinion, was an appointed time immediately before labor. The simplicity of the technique and the comparatively favorable condition of the patient in timely operations, he thought, entitled us to expect results in Cæsarean delivery quite equal to or better than the best records of laparotomy in disease.

**Compound Fractures and their Treatment** was the title of a paper by Dr. HERMAN MYNTER, of Buffalo. For many years the mortality in European hospitals in connection with compound fractures had been very great. It was Volkmann who instituted a radical change in the treatment of such injuries, and in 1877 he was able to report seventy-five cases, in some of which amputation was performed on the second day after the injury, all of them resulting favorably. His treatment consisted in thorough cleansing of the wound, with the removal of all dirt and dead or hopelessly bruised tissue, irrigation, and drainage. In fact, it was the application of antiseptic methods of treatment. The principle upon which the author treated such cases was that of converting a contused and lacerated wound, with its dirt, splinters of bone and crushed tissue, into a simple incised wound, all tissues being removed which were likely to undergo necrosis, and the wound thoroughly cleansed, even if it was originally only a punctured wound, and then closed like any other simple incised wound. No drainage-tubes were used and no silver wire. The limb was immobilized after closure of the wound, and the subsequent course after such treatment had in his experience been an aseptic one. The plaster dressing was retained from four to six weeks, and he was now treating many cases successfully in this manner for which in former years amputation would have been considered necessary.

Dr. LEWIS S. PILCHER, of Brooklyn, remarked that compound fractures, above all injuries, showed the advantages of antiseptic surgery. He thought that the chapters upon this subject were being rewritten. The directions of former years were to be, in most respects, discarded. The results obtained by the reader of the paper were ideal—better than could ever be expected by the profession at large. He believed that the danger in such cases lay not in the treatment received in the hospital, but in the first dressing made by the ambulance surgeon. This latter subject was one which heretofore had been too much overlooked.

Dr. J. H. PACKARD, of Philadelphia, referred to the occasional overlooking of punctured wounds in compound fractures because they were thought to be of minor importance. They were not of minor importance, and frequently signified a disorganized condition of the fissures. Such wounds should therefore be laid open and thoroughly cleansed, the general principle being to get at the bottom of all cavities. He objected to the use of plaster for the first dressing, preferring the ordinary antiseptic dressing with splints of felt or binders' board. A plaster dressing applied when the limb was swollen would be inefficient when the swelling had disappeared. He believed that all surgeons should aim at ideal results, such as had been obtained by the reader.

Dr. HAYD was familiar with the work of the reader of the paper and corroborated his statements in regard to the excellence of the method employed. It was an advance upon Volkmann's method in that drainage-tubes had been found unnecessary. The plaster dressing had not justified the objections referred to by the previous speaker in the cases which he had observed.

Dr. MYNTER emphasized his point of converting a contused into an incised wound, and also the possibility of obtaining healing, even in extensive wounds, without pus. The plaster dressing was placed outside a thin antiseptic dressing. He did not think hospitals were so much at fault as surgeons when healing did not take place. If a surgeon was thoroughly clean, cases such as those which were under discussion could be successfully treated even in very dirty hospitals. He did not think one should expect too much from ambulance surgeons, who were not men of experience in their work. The temporary dressing made by them should be removed as soon as possible, and not allowed to remain for hours as a matter of convenience to the surgeon.

**Intravenous Saline Infusion for the Relief of Shock and Acute Anæmia.**—Dr. PILCHER read a paper thus entitled. The subject was not a new one. The object of the proposed measure was to restore the circulation to full volume as soon as possible after the occurrence of shock or the loss of blood. Blood was not absolutely necessary to effect this end. There were three classes of cases in which the method was indicated: (1) those in which shock was the predominating influence, (2) those in which hæmorrhage and shock were combined, (3) those in which hæmorrhage was the predominating influence. In a condition of shock the blood pressure was observed to fall, vitality was lowered, and, if this state continued, syncope would result. Such a result should be anticipated by laying bare and opening the median basilic vein, and injecting not less than eight ounces of a weak saline solution. This quantity might not be sufficient and might be increased to a quart, or even two quarts, as in a case which was narrated by the reader. In any case it would be necessary to continue the injection until the volume and force of the pulse were measurably augmented by the rapid diffusion of the fluid. The operation was a simple one, the instruments required being a glass tip for introduction into the vein, a piece of rubber tubing attached to the glass tip, and a funnel

attached to the distal end of the tube. The funnel must have sufficient elevation to give the requisite degree of force to the fluid in entering the vessel.

(To be continued.)

## NEW YORK ACADEMY OF MEDICINE.

SECTION IN ORTHOPEDIC SURGERY.

Meeting of December 18, 1891.

Dr. SAMUEL KETCH in the Chair.

**Congenital Absence of a Portion of both Lower Extremities.**—Dr. JOHN RIDLON presented a boy, ten years old, who had been brought by Dr. Manning to the last meeting of the Hospital Graduates' Club. There was an entire absence of all the parts below the condyles of the femur, and just posterior to the extremity of each of these stumps was a fleshy mass, which probably represented the undeveloped digits. The boy could walk quite well on these stumps, and at present was wearing artificial limbs, but, as these caused pain, he had presented the boy with the hope that some suggestions might be offered as to the best way of treating the case. It was questionable whether an artificial leg with a joint at the knee could be applied to limbs of this length, and hence the question of amputation might properly be considered. Personally, he was in favor of applying artificial legs, without any knee joint, directly to the stumps without operative procedures.

Dr. W. R. TOWNSEND thought that the fleshy masses would interfere with the proper application of these artificial limbs, and hence favored removing them.

Dr. J. E. KELLY thought that the fleshy masses were undoubtedly the remains of the undeveloped lower portions of the limb. He thought their position the normal one *in utero*. He had seen within the last few months a somewhat similar amputation in the upper extremity, with rudimentary digits which had been capable of movement.

Dr. HALSTED MYERS, on examination, found a slightly movable bony mass between the condyles of the left femur, probably a poorly developed patella. He thought the case one of non-development, not amputation.

**Congenital Deformities of the Upper and Lower Extremities.**—Dr. MYERS presented a case and asked the opinion of the Section as to the value of operative procedures for the relief of the constrictions caused by amniotic bands.

Dr. KELLY thought that the phalanges of the great toes were perfect in this case, but that the digits had been suppressed, and development had taken place beneath the skin.

The CHAIRMAN referred to a child he had seen in which there had evidently been an attempt at amputation *in utero*. There was a deep constriction just above each ankle, more marked, however, on one side. The mother of this child, quite early in pregnancy, had been tipped by a cord which some boys had tied across the street, and it was thought that this maternal impression was responsible for the deformity. The child was able to walk with the aid of ordinary ankle supports.

Dr. TOWNSEND did not favor operating upon these constricting bands, for the cicatrix would cause further contraction.

**The Anatomy of the Foot, with Exhibition of a New Club-foot Shoe.**—The postponed discussion on Dr. J. E. KELLY's paper was opened by Dr. ROYAL WHITMAN, who said that the author had spoken of removing a wedge-shaped piece from the cuneiform bones, but as these bones were quite small, their dimensions varying from half an inch to an inch, it was evident that a cuneiform osteotomy on such bones would be impracticable. The calcaneum could, of course, be treated in this manner by cutting to a considerable depth, but such an operation was to-

tally unnecessary. When one recalled the fact that the astragalus was poised on the os calcis in unstable equilibrium, there seemed to be no reason for increasing this instability. Such operations might be allowable if it were true, as had been stated before in the Section, that the radical cure of flat-foot was impossible, and that all that could be hoped for was relief. He had seen more than 300 cases of flat-foot, and he believed that a radical cure without operation was not only possible but easy.

Dr. A. B. JUDSON said that the mechanical toy constructed by Dr. Kelly admirably illustrated the fact that human locomotion resembled the action of a wheel in motion, in which the legs were the spokes and the feet were the felloes, as pointed out by Dr. Holmes. That ordinary locomotion was a continual falling and a continual recovery was seen in the gait of a child learning to walk, and in the titubation of a drunken man, whose body inclined in a given direction and would fall if the legs and feet failed to make a timely movement forward to prevent a fall. He said that Dr. Kelly's apparatus took advantage of the weight of the body for the correction of the varus. It was well known that varus corrected to a certain point and held there was further corrected by the weight of the body applied in successive blows, as the child ran about. On the other hand, if the varus was reduced only to a point on the wrong side of the line between deformity and symmetry, each foot-fall was a blow increasing the varus. Dr. Cook, of Hartford, had shown a varus shoe at Washington last summer which had had attached to the sole a flat piece of steel extending outward a few inches to enable the weight of the body to act in a favorable manner on the deformity. He had seen a horse treated for some affection which made it desirable to prevent extension of the foot by the application of a horseshoe having a long posterior prolongation. The veterinary surgeon could attach his apparatus with absolute firmness to the foot, but in our patients the foot was apt to turn over inside of the shoe. As a rule, the weight of the body could be made more effective by the use of an apparatus having an upright extending up the leg, and a steel foot piece in which the foot was prevented from rolling by a strip of adhesive plaster.

Dr. R. H. SAYRE said that this succession of falls during the act of locomotion was well shown in instantaneous photographs of athletes running. The shoe exhibited by the author was doubtless intended for the treatment of club-foot in the later stages, when it was possible for the foot to be placed flat on the ground in a fairly good position. Before this stage the shoe could not be easily adapted to the crooked foot. The usefulness of this "snow shoe" was not so much on account of its shape as of the fact that there was a long lever on the outer portion of the foot which prevented the child from standing on this outer portion. In connection with this shoe, he had intended to exhibit a shoe which one of his patients had devised for his own use. His shoe had been made with the sole sloping outward for some distance, thus answering the same purpose as the snow-shoe. This patient had had adhesions and contracted tendons following infantile paralysis, so that the weight of the body had been unable to do more than prevent an increase of the deformity. The foot had only been brought straight by subcutaneous tenotomy and the use of very strong force applied by means of Bradford's instrument.

The CHAIRMAN said that many instances were recorded in which this principle of utilizing the weight of the body had been embodied in various kinds of apparatus. In some cases of equinus the patients had been allowed to walk without apparatus with the idea of utilizing this factor.

**A Consideration of some of the Affections of Tendon Sheaths and Bursæ, and their Relations to Injuries and Diseases of the Joints.**—Dr. ROYAL WHITMAN read a paper with

this title. He briefly described the structure and anatomical relations of bursæ and tendon sheaths, their diseases, and their appropriate treatment, calling attention to the fact that chronic disease of tendon sheaths was usually tuberculous in character, for which early removal was the only remedy. The relation of the tendon sheaths to the ankle and wrist joints, and their liability to injury in sprains and fractures, explained the symptoms—weakness, local pain, and limitation of normal motion—often persisting after such injuries. The importance of local massage and stimulation in the early stage, in order to prevent the formation of adhesions after secondary inflammation of tendon sheaths, was urged. In chronic and neglected sprains a careful examination should be made, and, if adhesions or contractions were present, treatment should be directed to a recovery of the normal range of motion. This result might often be accomplished by a forcible overstretching under anæsthesia, followed by massage and support. By such treatment patients disabled for many months might be relieved quickly and permanently. In conclusion, attention was called to the importance of slight injuries in childhood, which might be the starting-point of tuberculous disease, the diagnostic value of chronicity, and the necessity of careful observation and early treatment in suspicious cases.

Dr. JUDSON said that he had seen a case of tumor of the semi-membranosus similar to the one shown in the model. The child had been about six years old, and, under a purely expectant treatment, the tumor had disappeared in the course of a few months, leaving no deformity or disability.

Dr. TOWNSEND said that he had seen many of the cases referred to by the author, and he had been struck with the many and varied diagnoses which had been made upon them before they came to the dispensary. The diagnosis in the early stages was often difficult, especially when there was only a meager and often misleading history such as accompanied most dispensary cases. The importance of the diagnosis could not be too strongly emphasized, particularly as upon it depended a correct prognosis.

Dr. C. A. POWERS said that he inferred from the author's remarks on injuries at the lower end of the radius that he recommended confining the flexor and extensor tendons of the fingers in the treatment of Colles's fracture. He saw a large number of these cases with functional disability following this method of treatment, and he therefore preferred to use the long anterior splint for the first five or six days, and then to shorten both the anterior and posterior splint to the first row of the carpus, directing the patient to make very active use of the fingers. Four or five days after this he expected him to be able to shut the fingers well down into the palm.

Dr. KELLY said that in Dublin, the home and birthplace of Colles's fracture, the keel-shaped splint, which avoided injurious pressure on the thenar and hypothenar eminences was almost universally employed. The mode of development of the bursæ found on various points exposed to pressure was difficult to understand, unless we remembered that the peritonæum, which was the great areolar interspace of the body, had had a similar development from the connective-tissue structures. He was glad that the author agreed with him as to the position of the foot—viz., slight adduction with the foot at right angles to the leg. This slight adduction produced what he called "artificial talipes varus."

The CHAIRMAN said that he inferred from what the author said that he considered these bursal tumors of tubercular origin. He wished to dissent from this opinion, for many of them were benign and the result of injury.

Dr. WHITMAN explained that he had spoken of slow, chronic enlargement of the sheaths of the tendons of the wrist and hand

as tubercular. The deep-seated bursæ were favorably located for tubercular inflammation, and accordingly when they underwent chronic enlargement he preferred to treat them radically. He had only incidentally referred to the treatment of Colles's fracture. He did not consider the confinement of the fingers with vigorous massage and local stimulation the same as the confinement treatment which had been criticised during the discussion.

**An Improved Adjustable School Desk and Chair.**—Mr. E. E. HICKS exhibited a chair and desk which he had devised, and to which reference had been made in the recent discussion on the subject of the relation of faulty attitudes to lateral curvature of the spine. The desk and seat admitted of an independent vertical adjustment of four inches, which was manipulated by means of a key. The slope of the desk could also be varied to suit individual requirements. The desks and seats could be folded so as to occupy very little space, thus facilitating cleaning the school-room and allowing room for gymnastics. The seat and desk had a common base of support; a child using the desk, therefore, occupied the seat joined to the desk next behind. This improved desk cost only about fifty cents more than those now found in the market.

Dr. R. H. SAYRE thought this desk was a decided improvement on the usual style.

The CHAIRMAN thought that it might be desirable for a child already suffering from lateral curvature, but he did not believe that faulty attitudes at school were the cause of rotary lateral curvature.

#### **Tubercular Disease of the Vertebrae in its Early Stages.**

—Dr. R. H. SAYRE presented the second, third, and fourth lumbar vertebrae of a patient, showing a very early stage of tubercular disease. There was a cheesy mass in the third lumbar vertebra which had not yet broken down and ulcerated through into the cartilage. The points of junction between the second and third, and the third and fourth vertebrae were apparently normal. There was an extravasation of blood into the vertebrae. The history of the patient from whom these specimens were taken was quite interesting. A child suffering for some time from chills and high temperature had begun to have a peculiar posture and mode of locomotion and to suffer from abdominal pains. This had led to a diagnosis of spinal disease, but in a consultation with an orthopaedic surgeon this opinion had not been confirmed, the latter believing that the child was suffering from malaria. The symptoms not subsiding under the administration of quinine, the child had been brought to Dr. L. A. Sayre, who had concurred in the diagnosis of disease of the spine. At this time there had been some psoas contraction on the right side, with spinal rigidity and very slight pains. It could hardly be said that there had been a kyphosis; the lumbar spine had been straight instead of concave. The child had been placed in a wire cuirass. About a month later he had suddenly shown a temperature of 104°, with vomiting, photophobia, phonophobia, stiffness of the neck, and a rapid pulse. He had then been seen by the speaker, who had found an abdominal enlargement near the left side of the umbilicus, which could be separated by percussion from the spleen. It had been quite freely movable. Small doses of bichloride of mercury had been administered, and in a few days the temperature had fallen to 100° and had remained at this point, and the other meningeal symptoms had disappeared. There had been no colic indicating tubercular peritonitis. The child had become then even more anæmic than before, and the abdominal swelling had increased in size. It had seemed hardly possible that the mass could be a psoas abscess pointing in such an unusual position. After some time the mass had become larger and had moved toward the posterior surface of the abdomen. In consultation with Dr. W.

T. Bull, it had been decided to be inadvisable to operate. The child had died six days ago, and for a few days before death there had been slight jaundice. The post-mortem examination had shown that the abdominal tumor was formed by a tubercular mass which united the intestines into one large mass. There were no small miliary tubercles scattered over the peritonæum. One little band pressed upon the gall-bladder, and so accounted for the jaundice. The kidneys were firmly bound down with adhesions, and the left one was very large and waxy and its pelvis was much dilated. There was a large quantity of fluid in both pleural cavities, and there were cheesy nodules at the apices of the lungs. The heart was enormously thickened; the brain was not examined.

The CHAIRMAN thought that the symptoms described were more like those of an acute non-tubercular meningitis, as in the initial stage of the tubercular variety a high temperature was unusual, and the pulse was ordinarily slow or intermittent. Then, again, the subsidence of the symptoms was not in accordance with such a diagnosis.

Dr. KELLY called attention to the fact that in the early and late stages of tubercular meningitis the pulse was rapid, while in the intermediate stage it was slow.

Dr. RIDLON said that he inferred from the remark of the chairman that he shared in the general feeling in the profession that if a child survived, it was proof that the meningitis was not tubercular, and *vice versa*. He desired to express dissent from this opinion. Eight or nine years ago he had treated a boy who had suffered from a form of meningitis which several eminent consultants had considered to be tubercular; and they had an opportunity of seeing the patient a good many times. The patient was still alive, but he did not believe this proved that the diagnosis was incorrect.

The CHAIRMAN said that he had never seen one undoubted case of tubercular meningitis end in recovery, although he believed there were a few such cases on record.

Dr. H. W. BERG was not aware that there was any symptom, either subjective or objective, which would enable one to make a diagnosis between simple and tubercular meningitis. He thought that where there was a high temperature at the beginning of a meningitis, it was due to a series of eclamptic seizures which, by paralyzing the heat center of the body, allowed of a sudden rise of temperature.

Dr. TOWNSEND had had an opportunity of seeing a considerable number of cases of tubercular meningitis, almost all of which had been proved by autopsy to be tubercular, and he could not recall any case where there was an extremely high temperature at the beginning.

Dr. R. H. SAYRE said that he had looked upon the meningitis as tubercular, because of the very general tubercular infection. The child had looked as if it would die within a few days after the onset of these meningeal symptoms, and he had been much surprised when the acute symptoms had subsided so rapidly. The high temperature might have been due to the abdominal lesions. The extent of the abdominal lesions had been remarkable, as they had been younger than the disease in the spine.

#### AMERICAN LARYNGOLOGICAL ASSOCIATION.

*Thirteenth Annual Congress, held at Washington, on Tuesday, Wednesday, and Thursday, September 22, 23, and 24, 1891.*

The President, Dr. W. C. GLASGOW, of St. Louis, in the Chair.

**The Troublesome Symptoms caused by Enlargement of the Epiglottis, and the Advisability of reducing the Size of this Cartilage by Operative Measures.**—Dr. C. C. RICE, of New York, read a paper on this subject. (To be published.)

Dr. MULHALL: Did I understand Dr. Rice to state that he had seen cases of uncomplicated, non-syphilitic, non-malignant, non-tubercular, non-traumatic primary enlargement of the epiglottis?

Dr. RICE: Yes, I have.

Dr. MULHALL: Are they not uncommon?

Dr. RICE: I think they are.

Dr. MULHALL: I have asked this question because it is to me a novel fact that there can be a case of pure, uncomplicated, simple chondritis in any part of the body. I can understand enlargement of the epiglottis from surrounding catarrhal or other inflammation, which is the usual cause. I recall the case of a lady in St. Louis who had an unyielding, irritable cough. She went abroad a year ago and consulted a prominent laryngologist, who pronounced the cause of her cough to be a distorted and enlarged epiglottis, and he galvano-cauterized it. Following this there was much irritation of the epiglottis and swelling, with more cough. This lady died a week ago with pulmonary tuberculosis. She told me that the prominent laryngologist did not examine her lungs once. I can understand a large, pendulous epiglottis as a result of irritation; but I can not understand a primary non-specific enlargement of the epiglottis. It is new pathology to me.

Dr. S. O. VANDER POEL: I wish to emphasize the remarks of Dr. Rice regarding the unfavorable results following the galvano-cautery in cases of this kind. The use of the curette or sharp spoon has given me much more satisfaction. The pathological condition described by Dr. Rice, the hypertrophy of the cartilaginous elements, I am not familiar with, but I have seen enlargement, with more or less inflammation and hypertrophy, of the epiglottis in connection with enlargement of the tonsils.

Dr. JARVIS: I was much interested in Dr. Rice's remarks upon hypertrophy of the epiglottis. He explains a condition new to me—something I have never seen. The signs of congestion and enlargement from inflammation we are familiar with, but primary hypertrophy of the cartilage of the epiglottis is new. You may perhaps remember a somewhat similar condition, which was referred to in connection with our discussion of the enlargement of the septum narium at a former meeting. I then held that there might be an enlargement of this cartilage due to increase of cartilage cells, which could only be demonstrated by the microscope; and, upon making further investigation, discovered that inflammatory changes in the submucous tissue directly above the cartilage could be easily demonstrated. I think that, in all probability, in the enlarged epiglottis of Dr. Rice a similar condition will be found to exist. Change of form of the epiglottis may result from distortion and congestion. That we may have disturbance of function from these causes I am satisfied. I recall the case of a clergyman who came to me with a cough and difficult phonation. I found a swollen epiglottis, and applied cocaine in the manner recommended by Dr. Rice, and the patient experienced so much relief that he was enabled to resume his duties in the pulpit. There may be no direct advantage gained from the use of the galvano-cautery, but we must acknowledge that the psychical effect produced is often very great, whether this agent be applied to the hypertrophied epiglottis or to the tip of the nose. I believe it may have given relief from cough, but think it merely acted through the medium of the patient's mind. A much better substitute is to train patients to exercise their will, and in this way overcome the tendency to cough.

Dr. WAGNER: About ten years ago I read a paper before this society in which I reported a case of removal of the entire epiglottis for carcinoma by a subhyoidian incision, the first case on record. Before performing the operation, I considered the several methods, and came to the conclusion that removal

by the mouth of the *entire* epiglottis was impracticable. The patient experienced no ill effects after the operation, except a peculiar cough. A similar effect had been observed by an experimental physiologist at Harvard University in a number of cases upon which he had performed the operation. I have never seen a case of ordinary eatarhal inflammation of the cartilage, as described by Dr. Rice.

Dr. RICE: I certainly think that these cases of enlarged epiglottis are exhibitions of a chondritis, and can not see why we may not have cartilaginous inflammation and enlargement of the epiglottis as well as of the septal cartilage. I am at a loss to know why the gentlemen have not observed these enlarged epiglottides. In many cases I have found enlargement of the lingual tonsil to be the cause of the irritation and hypertrophy of the epiglottis, but not always, for in some cases the enlargement seems to be congenital. I do not believe that enlargement of the epiglottis is an unusual clinical condition, and this condition is almost as great a source of irritation in the larynx as is a small foreign body. That enlargement of the epiglottis and its contact with neighboring tissues produces distressing symptoms and demands appropriate treatment, I am sure must be admitted. Medicinal applications seem to be inadequate to reduce the size of the epiglottis.

**The Result of Treatment of the Upper Air-passages in producing Permanent Relief in Asthma.**—Dr. F. H. BOSWORTH, of New York, read a paper with this title as the opening of a discussion on the subject. (To be published.)

Dr. BEVERLEY ROBINSON: Mr. President, I merely desire to take up this subject again in order to affirm the opinions which I have endeavored to place before this association at previous meetings and before other societies, and which I have expressed in some of the medical periodicals of the day. I am glad, if I interpreted Dr. Bosworth's paper correctly, to learn that he has somewhat modified the views which he maintained several years ago. It is certainly remarkable for him to say that other conditions than those present in the nose take a prominent part in causing an outbreak of asthma. Certainly none of us take exception to his statement that he had by his treatment given relief to a certain number of cases. We merely do not accept the assertion that all cases of asthma arise in the nose; that in effect Providence has appointed that all cases of this kind should fall into the hands of the rhinologist and laryngologist, and that all cases of pure asthma should go to the specialist and to him alone. In a paper which I read before the Climatological Association in 1889 I endeavored to prove, and believe I did prove, that Dr. Bosworth's views were wrong from a broad general standpoint; that they were those of a specialist. I think that if Dr. Bosworth had followed up his cases he would have found a certain amount of the old trouble recurring at intervals. I am firmly of the belief that where there are frequently changes in the peripheral nerve fibers or central nervous system, a permanent cure is rare. Local conditions of the nose may at times justify an operation for removal of a source of irritation, but I wish to put myself upon record against the view that obstruction of the nasal chamber, or the effect of inflammation, is the usual cause of asthmatic attacks. I am opposed to such a limited view of the disease. While we may occasionally remove the source of a certain amount of irritation by the treatment of the nose, we do not remove the disease; relief may follow just as it sometimes follows the application of a blister between the shoulders. The relief may persist for a certain length of time, but after a while the condition producing the attack will return and the old disease reappear.

Dr. ROE: In all cases of asthma caused by disease of the nasal passages we should distinguish between those in which the asthma is dependent directly upon diseased conditions in the

nasal passages and those in which there is associated disease of other portions of the upper respiratory tract which have resulted from disease in the nasal passages and which often become independent centers of irritation in the production of asthma. As regards the ætiology of asthma, I believe that asthma proper is always dependent upon a diseased condition of the bronchial mucous membrane, and it is by reason of this abnormal condition of the bronchial mucous membrane that diseases in the upper air-passages so readily produce turgescence and swelling of the bronchial mucous membrane, as was first pointed out by Weber. I think that in those cases reported by Dr. Bosworth, where the attacks recurred, it was because he overlooked the diseased conditions in other portions of the respiratory tract after he had removed the disease in the nose. In this manner it is readily explained why in some cases asthma dependent upon nasal polyps will be readily cured by the removal of the polyps, while in other and quite similar cases the removal of the polyps will have but little or no effect in arresting the asthma.

Dr. WAGNER: In a brochure, published about ten years ago, on Habitual Mouth-breathing, I reported a case of nasal polyp which greatly obstructed the nasal respiratory passages. After removal by operation the patient had relief from asthma, from which he had long suffered. But I have seen since then so many cases of asthma with, so far as I could judge, perfectly healthy nares, and, on the other hand, so many cases of nasal polypi, deviation of the septum, hypertrophied mucous membrane, exostoses, etc., with no symptoms of asthma, that I have long since ceased to look upon the nose as a factor in this affection, or to recognize any connection between asthma and nasal disorders.

In regard to patients being benefited by removal to great altitudes, I have seen many that experienced no relief by the change. I might refer to one, a New York physician, a sufferer from asthma, who went through the usual course of painful local treatment of his nose; not experiencing relief, he tried change of climate—to the South, thence to the West Indies, thence to Colorado Springs, thence to New Mexico, and finally to the sea level in southern California, where he not only found relief, but has quite recovered.

Dr. SHURLY: I think that the ground has been pretty well covered in the discussion. I remember very well the paper that Dr. Bosworth read before the Climatological Association, some years ago, in which he gave his opinions on the causes of asthma and its treatment. I remember that the same points were brought out in the discussion then that have just been considered. Since many cases of disease of the nose occur without asthma, and *vice versa*, we are still held to the old conclusions or doctrine that two causes must co-exist to produce asthma: Firstly, a point of irritation, which may be in any part of the body; and, secondly, a peculiar predisposition of the nervous system of the individual. Such treatment as Dr. Bosworth proposes is necessary in a certain number of cases; but the physician who neglects to treat the nervous element would not do his whole duty to the patient. In any case, if it is associated with a hypertrophic enlargement which gives rise to irritation, this should be removed. In a paper which I wrote some years ago I recorded the results of some experiments upon dogs in relation to this subject, one of which was that, by irritating the peripheral nerves of the respiratory tract with an electric current, symptoms were produced resembling asthma. This does not invalidate the view that asthma may be due in some cases to vascular excitement, or congestion, in certain parts of the body, because the physical conditions may be about the same. I regret to say that in many cases the pathology and ætiology can not be made out, and such I recommend to go to a more suitable climate; it may be St. Paul, or southern California, or Macinac, if it is possible for them to go.

Dr. GLASGOW: We must remember that in the surgical treatment of asthma there is a psychical factor; as an attack can often be broken by a powerful emotion, the application of the electrical cautery has a similar effect. The method of Duclos at the beginning of the century was based upon this, the effect being brought about by the application of aqua ammoniæ to the pharynx. I read a paper before this society upon the effect of applications to the larynx in breaking up a paroxysm. I called attention to the use of carbolic acid and the insufflation of certain powders into the larynx, and showed that this was immediately followed by a cessation of the attack of asthma. I have also seen an attack relieved by simply cleaning the nostrils, by the removal of a polypus, and even by spraying the cavities with a simple alkaline wash. One case made a profound impression upon me. I applied a strong solution of carbolic acid to the larynx during the height of the attack, and the man has never had an attack of asthma since, and that was three years ago. The statement of Duclos, together with my own experience, has made me believe that the results in some of our patients are largely due to the powerful psychical impression. Like all nervous affections, asthma is erratic in its course and appearance. The asthmatic habit is stronger in some than in others, and the same methods of repression will not be equally successful in all cases. The habit is unquestionably sometimes kept up by points of irritation in various parts of the body, and relief of this irritation is necessary before permanent relief can be obtained.

Dr. MULHALL: I think that we are arguing away from our original standpoint. What Dr. Bosworth was referring to was simple nervous asthma. My objection to the statistics presented is that they are not properly studied. When Mr. Hutchinson, of London, recorded a case, he took the address and visited the patient afterward to learn the results of treatment. In Dr. Bosworth's list there are a number in which the result is not given, because the patient failed to come back to him. This invalidates his percentage of cures. I remember when Dr. Daly read his paper on galvano-cautery in the treatment of hay-fever, I was impressed by it, and during the next season I treated twelve cases in this way. I took the address as well as the name of each patient, and subsequently I called upon them and found that, while they were surprisingly relieved, they were not cured. That nasal disease is one of the causes of nervous asthma I can not deny, but that it is the sole cause of the disease is simply absurd. Patients with nasal polypi are many of them free from asthma or the two diseases may coexist. The pathological irritation may start from the nasal mucous membrane, and cause reflex contraction and symptoms in parts of the body other than the bronchi. In one case that I recall there was a difficulty in passing urine, a spasmodic stricture, which was immediately relieved by the removal of nasal polypi. This patient had what might be called "vesical asthma."

I agree with Dr. Bosworth in his statement that some cases of bronchial asthma are cured by the removal of disorder from the nose, such, for example, as hypertrophic rhinitis. In two cases that I recall where there was associated enlargement of the anterior end of the middle turbinated bones I have the record; one was done five years ago and the other three years ago. I took the patients' addresses and have verified the result in each case as being complete and lasting successes. The position I take with patients is this: I tell them that I have been able to find nothing wrong in the body except this disease in the nose, and by its removal the asthma may be cured. I by no means promise that it will cure the asthma; it may do so and in many cases will do so, but I can not promise that it will in any particular case.

Dr. INGALLS: From my own experience and what I have

learned from others, I am satisfied that in a large percentage of cases operations on the nose, however complete, fail to relieve asthma. I have seen three cases in which there was a peculiar and interesting connection between nasal polypi and asthma. In all of the three where polypi were confined to one naris, the patient alleged that the asthma was also confined to the same side.

Dr. ROBINSON: I wish to call attention to cases of asthma of malarial origin, and would state in the first place that I am to read before the Climatological Association a paper on The General *versus* Local Treatment of Catarrhal Inflammations of the Upper Air Tract, in which these cases are reported. They came under my observation with symptoms of asthma some years since. I have now reason to believe that in these instances examination of the blood would show the presence of the hæmatozoon malarie. There is not invariably in such cases enlargement of the spleen or other physical signs of malarial poisoning. I have proceeded upon the conviction established by symptoms to show the connection between the respiratory disorder and blood-poisoning. By acting in this manner, I have been able also to note that treatment directed to the condition of the blood was followed by relief from the asthma. In cases of different order where some nasal source of irritation was present the *Hæmatozoon malarie* was not found.

One other point I would like to mention. A very valuable essay was read by M. Noel Guéneau de Mussy some years ago upon the effects of enlargement of the bronchial glands in causing asthmatic attacks in children, and physical examination has proved to me the correctness of this statement. Why may not such a condition be sometimes present in cases of asthma in adults? One reason why the iodide of potassium has such remarkable value in some of these cases may be explained by the presence of hypertrophied lymphatic ganglia. I think that in those cases where there are hypertrophies of the nose, operation does good by giving freer respiration and relieving congestion.

Dr. BOSWORTH: I seem to have been exceedingly unfortunate in my choice of words, else I should not have been so misunderstood. The real subject of my paper has been largely passed by in the discussion. Dr. Mackenzie has come to the conclusion that I affirm that I can cure emphysema. I made no reference to this affection. I did not say that all cases of asthma were caused by nose diseases. That would be a gross misstatement; nobody believes it. To state that because hypertrophic rhinitis does not always cause asthma it never causes asthma, that because nasal polypi do not always cause asthma they never cause it, scarcely rises to the dignity of discussion. The old view is that asthma is caused by spasm of the bronchial muscles. I do not believe that the bronchial muscles have anything to do with it. I believe that the vaso-motor theory of Weber is the correct one; and if any gentleman here would do me the favor to read the paper which I prepared three years ago I think that he would agree with me. I hold that there are three causes of asthma, as I stated in my paper. This does not conflict with the views of Hyde Salter and others. With regard to the cases where there is enlargement of the heart or disease of the liver or kidneys, I say that these are conditions which aggravate and keep up the disease. I did not say that the nose was the only cause, and that its treatment was the only treatment; but I will say that in nineteen out of twenty cases, if we pay attention to the nose and remove any disorder existing here, we shall do better by our patient than if we simply rely upon iodide of potassium and routine treatment with the usual remedies for asthma.

Dr. JONATHAN WRIGHT, of Brooklyn, read a paper on this subject. (See vol. liv, page 711.)

Dr. MULHALL: I did not hear all of Dr. Wright's paper, but I agree with his conclusion. In my specimen and report presented last year I took occasion to state that I doubted very much the propriety of Hopmann's statement that he had found so many cases of true papilloma. I removed such a growth, just before I left home, attached to the columella. It resembled a bunch of grapes, was pedunculated, and completely blocked the nostril. I found upon examination that it was a true papillary fibroma—the only case I have ever seen. I wondered why I had never seen any before when Hopmann had seen so many, but Dr. Wright has probably furnished the true explanation.

Dr. SHURLY: I was very much interested in this truly valuable paper we have just heard read; it is valuable for its investigations in the fields of histology and pathological anatomy. In these papillary growths we have another illustration of the law of evolution and the analogy between the animal and vegetable world. This process of *budding*, so prominently belonging to vegetable growth, is nevertheless destined in a few years to be accepted in explanation of the growth of tumors, a vegetable process manifested, as it were, by animal tissues.

Dr. J. SOLIS-COHEN: I believe that macroscopically a distinction may be made in many cases between papillary and other tumors in the contrast between the size of the growth at its base and at its attachment, the former being pedunculated. I think something of this kind was what led Hopmann astray. I remember that Dr. Jarvis some some years ago pointed out this contraction at the point of attachment of papillomata, and I think that this led to the invention of the snare.

Dr. JARVIS: I had something to say upon this point last year. The only case of true papilloma that ever came to my notice I reported at that time. I have seen a number of cases, in both public and private practice, such as Hopmann describes, but I recall one case of true papilloma, and this was at the margin of the vestibule at its junction with the skin. I have also seen that condition of the turbinated bone alluded to by Dr. Solis-Cohen which Hopmann evidently mistook for a true papilloma. In the nostril proper I have never seen an instance of independent papilloma, but I have seen them in connection with other growths, such as mucous polypi, and think that they may easily be overlooked. I regard these as secondary to the polypi, and as not requiring special treatment. As remarked by Dr. Solis-Cohen, it is of more interest to us and to those in general practice to establish points of diagnosis upon macroscopic distinctions rather than microscopic. I pointed out in a former communication that chronic acid afforded a special means for distinguishing papillary from other growths. In papilloma the application of chromic acid to the base of the growth creates a peculiar eschar.

Dr. MACKENZIE: At our meeting a year ago I said that true papilloma of the nares was rare, having myself seen only two cases. It is more common anteriorly than in the posterior nares. It is probable that Hopmann has mistaken for papilloma those papillary vegetations characteristic of the transition stage from hypertrophic to atrophic rhinitis. It is not unusual for patients to expel these masses spontaneously, thereby gaining relief from previous nasal obstruction. As a matter of fact, however, this process of detachment and expulsion is degenerative, and the final condition of atrophy is worse than that which preceded.

Dr. WRIGHT: There is very little to be said in closing the discussion. I think that Hopmann was not so much led astray in his diagnosis as he was wrong in his nomenclature; he knew what they were, but called them by an objectionable name. If this is permitted, it introduces confusion into laryngological literature. I was not aware that he had recanted in a more re-

cent publication, as I have not followed up the subject very closely. I must take exception to the statement of Dr. Jarvis that it is not very important to make a microscopical diagnosis between these tumors and others which resemble them. I think it very important.

Dr. JARVIS: I meant from a therapeutical point of view.

Dr. J. SOLIS-COHEN: If the word papilloma is to be rejected, perhaps some title such as "dendritic vegetations" would be a good substitute.

Dr. WRIGHT: I think it would be better to abandon the term papilloma altogether:

(To be continued.)

## Book Notices.

*A Practical Treatise on the Diseases of the Ear*, including a Sketch of Aural Anatomy and Physiology. By D. B. ST. JOHN ROOSA, M. D., LL. D., Professor of Diseases of the Eye and Ear in the New York Post-graduate Medical School and President of the Faculty, etc. Seventh Revised Edition. New York: William Wood & Co., 1891. Pp. xxii-741.

MANY physicians will greet this work as an old and well-tried friend, reliable and trustworthy. It has changed very little since its last appearance, though some additions have been made, mainly in the portion devoted to middle-ear diseases.

It is a work which is not only valuable to the specialist, but also peculiarly adapted to the needs of the general practitioner who is situated at a distance from a specialist and must either let aural diseases work their disastrous results upon his patients or learn to treat them himself. To the physician who prefers to do the former, suggestions are useless, but to him who desires the latter, this work is to be strongly recommended as a safe and conservative guide.

*Cookery for the Diabetic*. By W. H. and Mrs. POOLE, with a Preface by Dr. PAVY. London and New York: Longmans, Green, & Co., 1891. Pp. vi-64.

THIS little book will lift a load from the mind of every physician who has a serious case of diabetes to manage. He knows how soon apparently slight restrictions in diet become irksome and how often articles of themselves harmless are rendered injurious by the cooking. He has felt the need of formulas by which his patients' diet might be rendered not only harmless but palatable. A list of prohibited and permissible articles is not sufficient, but it is all that is usually given. This book is a recipe-book designed not for the physician's library, but to be sent to the cook in the kitchen. The receipts are evidently practical and, having the sanction of Dr. Pavy, may be relied upon as harmless. Some are original; others are modifications of well-known receipts, while some are simply changed by the use of saccharin instead of sugar.

### BOOKS, ETC., RECEIVED.

*Atlas of Clinical Medicine*. By Byron Bramwell, M. D., F. R. C. P. Edin., F. R. S. Edin., Assistant Physician to the Edinburgh Royal Infirmary. Vol. I. Part III. Edinburgh: T. & A. Constable, 1891. Pp. 97 to 140.

*The Principles of Bacteriology: a Practical Manual for Students and Physicians*. By A. C. Abbott, M. D., First Assistant, Laboratory of Hygiene, University of Pennsylvania, Philadelphia. With Illustrations. Philadelphia: Lea Brothers & Co., 1892. Pp. viii-13 to 263.

*The Diseases of the Mouth in Children (Non-surgical)*. By F. Foreh-

heimer, M. D., Professor of Physiology and Clinical Diseases of Children, Medical College of Ohio, etc. Philadelphia: J. B. Lippincott Company, 1892. Pp. vi-8 to 199. [Price, \$1.25.]

The Complete Medical Pocket-Formulary and Physician's Vade-Mecum: containing upward of 2,500 Prescriptions, collected from the Practice of Physicians and Surgeons of Experience, American and Foreign, arranged for Ready Reference under an Alphabetical List of Diseases; also a Special List of New Drugs, with their Dosage, Solubilities, and Therapeutical Applications; together with a Table of Formulæ for Suppositories; a Table of Formulæ for Hypodermic Medication; a List of Drugs for Inhalation; a Table of Poisons with their Antidotes; a Posological Table; a List of Incompatibles; a Table of Metric Equivalents; a Brief Account of External Antipyretics, Disinfectants, Medical Thermometry, the Urinary Tests; and much other Useful Information. Collated for the Use of Practitioners by J. C. Wilson, A. M., M. D., Physician to the German Hospital, Philadelphia. Philadelphia: J. B. Lippincott Company, 1892. Pp. x-11 to 261. [Price, \$2.]

Diseases of the Bladder and Prostate. By Hal. C. Wyman, M. Se., M. D., Professor of Surgery in the Michigan College of Medicine and Surgery, Detroit. Detroit: George S. Davis, 1891. [The *Physicians' Library*.] [Price, 25 cents.]

Stricture of the Rectum: a Study of One Hundred and Thirty-eight Cases. Second Edition, enlarged. By Charles B. Kelsey, M. D., etc.

Four Congenital Tumors of the Head and Spine, all submitted to Operation. (Clinical Lecture delivered at the Jefferson Medical College Hospital.) By W. W. Keen, M. D. [Reprinted from *International Clinics*.]

Jacksonian Epilepsy; Trephining; Removal of Small Tumor, and Excision of Cortex. By Charles K. Mills, M. D., and W. W. Keen, M. D. [Reprinted from the *American Journal of the Medical Sciences*.]

Considerations upon Medical Hæmorrhage surgically treated; with a Successful Case, by a New Technique, of Saline Infusion for Severe Hæmorrhage. By Robert H. M. Dawbarn, M. D.

Remarks Introductory to a Discussion on Acute Diffuse Peritonitis. By A. L. Carroll, M. D. [Reprinted from the *Transactions of the New York State Medical Association*.]

Medical Ethics gone to Seed. By James H. Bell, M. D., Philadelphia. [Reprinted from the *Medical News*.]

Dental Infirmary Patients. The Use and Abuse of Dental Charity. By Richard Grady, M. D., D. D. S., Baltimore. [Reprinted from the *Journal of the American Medical Association*.]

Microscopical Diagnosis of Tuberculosis. By Paul Paquin, M. D., Battle Creek, Mich.

The Situation and Climate of Asheville, N. C. By H. Longstreet Taylor, A. M., M. D., Asheville, N. C. [Reprinted from the *Lancet-Clinic*.]

The Results of the Shurly-Gibbes Treatment of Tuberculosis at Asheville, N. C. By H. Longstreet Taylor, A. M., M. D., Asheville, N. C. [Reprinted from the *Therapeutic Gazette*.]

What can be done in Cerebral Surgery. Remarks based chiefly upon Personal Experience in Twenty-three Cases. By E. Lanphear, M. D., Kansas City, Mo.

A Clinical Study of One Hundred and Forty-two Cases of Heart Disease in Children. By Floyd M. Crandall, M. D. [Reprinted from the *Archives of Pediatrics*.]

Tenth Annual Report of the Hospital for Women and Children, Newark, N. J., December, 1891.

De la chloroformisation à doses faibles et continues. Par le Dr. Marcel Baudouin. [Extrait de la *Gazette des hôpitaux*.]

Transactions of the American Gynecological Society. Volume XVI, for the Year 1891.

Kemp & Co.'s Prescribers' Pharmacopœia. A Synopsis of the more Recent Remedies, Official and Unofficial, with a Therapeutic Index and a Résumé of the B. P. Additions, 1890. By a Member of the Pharmaceutical Society of Great Britain. Second Edition. Bombay: Kemp & Co., Ltd., 1891. Pp. xi to 429.

Thirty-sixth Annual Report of the Executive Committee of the Hartford Hospital. Presented to the Directors at their Annual Meeting, December 16, 1891.

## New Inventions, etc.

### A NEW HYPODERMIC-SYRINGE NEEDLE.

By W. J. P. KINGSLEY, M. D.,  
ROME, N. Y.

For many years I have used the common form of hypodermic needle very extensively. During this time I have always been greatly inconvenienced by the tendency of the channel to clog easily. This is not only very annoying, but occasionally of serious importance in an urgent case. Within the past year it occurred to me that a needle

with a conical channel, having the smallest opening attached to the syringe, could not clog. Several months ago Messrs. George Tiemann & Co., of New York, made a few needles according to my design. None of these have ever clogged, although thoroughly tested, and they have proved so satisfactory in every way that I desire to give the profession the benefit of this improvement. Fig. 1 shows the regular size. Fig. 2 shows an enlarged view, which will be more easily understood.

## Miscellany.

The Vernacular Medicine and Surgery of Japan.—Dr. Benjamin Howard contributes the following article to the *Lancet* for January 16th:

In aptitude, adaptation, and enterprise the Japanese have shown a decided superiority over all other nationalities of the Orient. These qualities, added to great delicacy of manipulation, have made them in art conspicuous throughout the world. It is but natural to expect, therefore, that they should be found to have arrived at something, both in medicine and surgery, which the nations of the West might find to be an acquisition. The earlier Japanese medicine dates back to the "Shindai," or divine age, many centuries before Christ. The Chinese, as early as 218 B. C., found their way among the Japanese doctors with medical books dating back, it is alleged, to 2737 B. C., and the influence of Chinese medicine upon Japanese medicine has continued to be a controlling one up to the recent introduction of European medicine now in vogue. As it is difficult to disentangle that past which is of Chinese origin, I include in the vernacular medicine and surgery of Japan all which pertained to its general practice, say, forty years ago, and which still pertains to the practice of about 30,000 out of the 41,000 physicians now practicing throughout the empire. Of the 30,000 of the old vernacular school, one of them is still on the list of the Court physicians and maintains a high reputation.

The impression throughout Europe that colored papers, exorcisms, etc., are the basis of Chinese and Japanese medicine is erroneous. I have myself seen nearly 2,000 books by these people, covering most of the departments of medicine, but among which materia medica occupies altogether the leading place. In these books are the doctrines of the successive schools, strikingly like some of those which in past centuries existed among our own ancestors. The successive medical colleges have always had a professor of astrology, but the solid fact remains that the materia medica has included among its several hundred remedies a large number of those used by ourselves, and these are not only vegetable, but animal and mineral, in the latter class mercury being prominent. Surgery became a separate branch as long since as the seventh or eighth century. Tube acupuncture needles, so comparatively new with us, have been in use here since A. D. 1688. Centuries ago one of their authors wrote: "When medicines are ineffectual as well as acupuncture and the cantery, the abdomen and back may be opened, the stomach and intestines be washed, etc." A narcotic mixture employed on such occasions contained *Datura alba*, aconitum, etc.

As the history of medicine in Japan once included so much which seems substantial, I have inquired with much care among practitioners of the old or vernacular school—all of whom were in practice before 1876—hoping to discover something in their practice now which would be a veritable addition to the medical resources of our European brethren. I am sorry to have to say that the result of my search has not met my anticipations. As far as I have been able to discover, the vernacular practice of Japan to-day, over the entire length and breadth of the empire which I have traversed, is entirely empirical. Rhachitis being unknown, and the life led by the women being so much more natural than in Europe, obstetrics may scarcely be said to be needed, and certainly does not exist.

Syphilis, which came here from China in 1630, is treated in a manner which is the same in principle as the treatment I have seen practiced in Nubia, where the patient, for several hours at a time, buries all the parts of his body except his head in the hot sands of the desert. In this excessively volcanic country the various hot springs which abound, and some of which are exceptionally hot, are the sovereign remedy. In these baths, some of which are fully exposed to public view, whole families, entirely nude, pass a large part of the time during their visit to the particular spa. In several cases I have not seen, but I have been told by the patients, of results from them which certainly seem remarkably good. In acupuncture, which, as I have said, has been practiced by the Japanese for many centuries, they exhibit very delicate manipulation. For six seng (3*d.*) one of the blind practitioners of this art will, without pain, insinuate a long needle into your stomach, intestines, arms, legs—almost any part except the eye and the brain. The conditions for which it is held in particularly high esteem are flatulence and colic; next, perhaps, in order for neuralgia and rheumatism of the joints. From my own experience I can say it is almost absolutely painless. The points to be penetrated are not entirely arbitrary, but are determined by astrological indications. It is a noticeable experience to see one of these poor blind men take from the folds of his "kimono," or robe, a case of beautifully bright long needles of gold, steel, or silver, and with the *nonchalance* of the Oriental, and without the slightest pause in his conversation, to see him burying his needles two, four, or six inches in various parts of your person in a way which would astonish a European professor of surgery. I mention this practice only as a pretty display of manual dexterity, not as a practice to be imitated. There is one medical procedure, however, in which the Japanese can teach us something in every particular. I refer to their manner of practicing massage. For reasons sufficiently apparent, the number of blind in Japan, as in all Eastern countries, is enormous. Every blind boy or girl is expected to join the *oue* guild, which is exclusively their own, and be an "ammah." With their small hands and supple limbs they give to massage a variety and a delicacy not approached even in India. To what extent anatomy enters into their training I do not know, but no duly qualified surgeon could seem to be more intimately acquainted with the formation of the joints and the course of the nerves as a guide to manipulation. As to percussion, they obtain it by a semi-rotation of the hand with a velocity so great as to make the movement almost invisible. The deeper structures external to the joints they get at with the olecranon process of the naked elbow, which, by an equally rapid movement of the forearm, reaches every interstice with a force regulated with the greatest delicacy. For the muscles of the back, as in lumbago, the "ammah" frequently use their feet, with which they are almost as dexterous as with their hands. When great force is desired this is very efficient. Plain rubbing, which is the principal part of massage in Europe, would be beneath their dignity. Nearly every one of their various manipulations includes some delicate manoeuvre which excites one's surprise and admiration. So common is massage in Japan that on arriving at a hotel—next to the tea, which is always immediately brought—the "ammah" is the individual who will surely appear. For the superficial or general massage at such time the tariff price is six seng (or 3*d.*); but a European is expected to pay two or three times as much as that, unless he can talk Japanese, in which case he generally does not. I have had massage in Sweden, which I thought perfection; I have had it in Turkey, which I thought otherwise; I have had it in India, and found it in most instances too rough and indiscriminate;

but with a good "ammah," or masseur in Japan I have had but one regret, which is that my friends at home could not share my advantage.

Another lesson we might learn from the Japanese with probable advantage is the more general use of the moxa. For almost any pain whatsoever, if persistent and if at all deep seated, the remedy throughout the country is the moxa. Whereas with ourselves the moxa is, even with a surgeon, a very unusual remedy, its use here is one of the female accomplishments in almost every household. A cone of cotton-wool previously saturated with a decoction of the *Artemisia vulgaris latifolia* is placed upon the part concerned, and, being lighted, is allowed to slowly smolder to ashes. It leaves a superficial eschar, which seems to heal without special attention. The performance is often seen going on in passing a house, a woman operating on a man, woman, or child, and dressing the patient's hair, perhaps, at the same time. I have therefore inferred the procedure is much less painful than might be supposed. The sore is clean, exactly the size wished, and must often be a very useful counter-irritant. In the public baths I have counted on men, women, and children as many as thirty or forty discolored spots from this cause, a row being commonly seen on either side the spine, and many other marks on the limbs, especially in the vicinity of the joints. To get the same amount of counter-irritation, we should certainly disable the patient from any active occupation and compel a good deal of inconvenient dressing, all of which, if the counter-irritation was to be maintained, would require repetition. In hygienic matters the Japanese have everywhere a habit which also may have a lesson for us. In their nightly bath and morning wash the water is never cold, never warm, but always as hot as it can be borne. To foreigners this habit seems very surprising, but the most inveterate Englishman, if he stays in the country long enough, abandons his cold tub in its favor. The cold-taking which it is suspected must follow it is found not to occur if the water has been hot enough. This heat is maintained by a little furnace beneath the bath. In the bath the bather or bathers take a prolonged soaking, the washing proper being done on the bath-room floor; then follows a second and final soaking, drying with towel, and a lounge in bathing wrapper. This habit seems to promote softness and suppleness of the skin, and by persons inclined to rheumatism is soon found to be altogether preferable to the cold bath in every particular. The poorest of the Japanese hear of a cold bath with amazement, and would be sure the man who used it must be a barbarian. With respect to the superiority of the hot bath over the cold, I have come to find that in my own case certainly the Japanese are right.

*The Paper Ice-bag.*—From a pocket handkerchief to an umbrella it is difficult to say what is not made out of paper, and everything made out of paper is comparatively cheap. The ice-bag is a very favorite remedy, both in private and hospital practice. The ice is generally applied in bags suspended so that the patient may get the cold from it without its weight coming upon the affected part. These pretty little bags are always made of thin paper. They are much cheaper than the oil silk used by ourselves in that, whether they become broken or not, they can be frequently renewed, and this, in a large hospital with surgical cases, is an important consideration. The texture is softer, it adapts itself better to the parts to which it is applied, and in a private patient one of these paper ice-bags will easily last in constant use for several days. They would be a valuable acquisition in English hospitals. I inclose one of them that the editors of the *Lancet* may form their own opinion of it.

It will be observed that the only things I have thought worth recommending are rather outside than inside the lines of strict medicine and surgery. It would seem that the decline in medicine must have been as great as the decline in the prevailing religions; hence the alacrity with which the foreign systems of both were seized by this hungry people as soon as presented. The Japanese massage, then, the Japanese bath, and the Japanese paper ice-bags are things which might certainly be regarded in Europe as useful acquisitions.

**The late Sir Morell Mackenzie.**—Dr. Arthur G. Root, of Albany, writes as follows:

Again has the messenger of death called from among our ranks a

noble leader. A bright star has ceased to shine in its earthly firmament. Again a voice which has bespoken words of instruction, of sympathy, and encouragement to so many has been hushed. Seldom has the medical profession throughout the world had such cause to mourn, seldom have we felt a loss as deeply as we now feel in the death of Sir Morell Mackenzie.

A man of great originality, he has given to the profession and world at large much that shall perpetuate his memory.

A man of a strong personality, possessing a sensitive and a sympathetic nature, throughout his life, the nobility, the power for good, the almost divinity of the profession of which he was a representative, was always uppermost in his mind. Few men at fifty-eight can look back upon a life so full, so rounded, and so complete. Proudly and unflinchingly might such a spirit enter the shadows, for for such there is a light beyond. Happy is he of whom it can be said that those who knew him best loved him most.

As one who has known the value of that close relationship, as one who has felt the ennobling influence of that untiring devotion to duty, I feel most keenly the loss which has come to us. Grandly he lived, triumphantly he passed away, and deep within the hearts of thousands remains a loving memory.

**The Necessity of Pure Drinking-water.**—It is evident that the necessity of using absolutely pure drinking-water can not become too strongly impressed on the public mind, but water in that condition is provided by very few communities. Hence the public are availing themselves of bottled natural mineral waters to a great extent, especially Apollinaris, which is of recognized purity, for its long-continued and world-wide use attests its merit. Where such waters can not be obtained, the ordinary drinking-water, if the least suspicion attaches to it, should be boiled before using. Precautions should be taken at all times of the year. It is often thought that in early spring, when rivers are swollen by melting snow, river water is purer and safer than in summer or fall. Recent experiments, however, have shown that the number of bacteria in the water supply increases greatly while the snows are melting on the uplands. Ice also is known to be a frequent source of poisoning; hence, while the water that is used may be pure, the ice that is put into it often renders it noxious.

**The Physician and the Painter.**—The *New York Times* quotes the following from the *Pall Mall Gazette*:

Here is a good story of a doctor and a painter's wife. The doctor's name does not appear, but the painter was Meissonier. Mme. Meissonier sent for the family physician in a great hurry. He came, thinking some illness had overtaken the artist. But it was not the artist; it was only a lap-dog. He pocketed his pride and attended the patient, who soon recovered. At the end of the year the bill came in, but there was no item for attendance on a dog. Mme. Meissonier noticed the omission and told the doctor to charge. He would not charge; he said he could not charge; he was not a vet. He was very glad to be kind to the dog, etc. The lady insisted. Well, said the doctor, the hinges of my garden gate are rusty; ask M. Meissonier to bring his brush and paint them for me.

**The German Medical Congress.**—The Eleventh Congress for Internal Medicine will be held in Leipzig, on the 20th, 21st, 22d, and 23d of April, under the presidency of Professor Curschmann. The programme announces reports on Grave Anæmic Conditions, by Dr. Biermer, of Breslau, and Dr. Ehrlich, of Berlin; and on Chronic Hepatitis, by Dr. Rosenstein, of Leyden, and Dr. Stadelmann, of Dorpat; and the following papers: On the Causes of Immunity from Infectious Diseases, and on their Treatment, by Dr. Emmerich, of Munich; On Uræmia, by Dr. Peiper, of Greifswald; On the Results of Suggestive Therapeutics, by Dr. Binswanger, of Kreuzlingen-Constantz; On the Consequences of the Excision of Large Portions of the Spinal Cord (a Report of Observations on Dogs by Dr. Goltz and Dr. Ewald), by Dr. Goltz, of Strassburg; On the Etiology of Chronic Heart Diseases, by Dr. Schott, of Naumburg; On so-called Hepatic Colic and False Gall-stones, by Dr. Fürbringer, of Berlin; The Treatment of Alcoholism, by Dr. Vucetic, of Mitrovitz; Further Contributions on Diabetes Mellitus after Removal of the Pancreas, by Dr. Minkowski, of Strassburg; On the Treat-

ment of Carcinoma, by Dr. Adamkiewicz, of Cracow; The Various Forms of Pneumonia, by Dr. Finkler, of Bonn; On the Secondary Changes in the Circulatory Organs in Renal Inadequacy, by Dr. Israël, of Berlin; On the Therapeutic Value of the Transfusion of Blood in Man, by Dr. Landois, of Greifswald; On the Pathology of the Bilharzia Disease, by Dr. Rüttemeyer, of Basel-Riehen; On Hemorrhagic Infarcts of the Lungs, by Dr. Grawitz, of Greifswald; On the Cure of Tuberculosis and on the Biology of the Tubercle Bacillus, by Dr. Klebs, of Zürich; Investigations of the Causes of Immunity, and of Recovery, especially in Pneumonia, by Dr. G. Klemperer, of Berlin, and Dr. F. Klemperer, of Strassburg; On Immunity from Infectious Diseases, by Dr. Buchner, of Munich; On Subcutaneous Transfusion of Blood, by Dr. von Ziemssen, of Munich; On the Ratio of the Danger of Infection to its Actual Occurrence in Tuberculosis, by Dr. Wolfi, of Reiboldsgrün; On Intestinal Disinfection, by Dr. Stern, of Breslau; Observations on Diabetes Mellitus, by Dr. Leo, of Bonn; and On Circulatory Disturbances in the Kidneys, by Dr. Schreiber, of Königsberg. Dr. von Jaksch, of Prague, Dr. Ebstein, of Göttingen, Dr. Gerhardt, of Berlin, Dr. Goppert, of Bonn, and Dr. Löffler, of Greifswald, are announced to read papers the titles of which are not given.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

Original Communications.

WHAT CAN WE EXPECT FROM THE SURGICAL TREATMENT OF EPILEPSY? \*

By B. SACHS, M. D.,

PROFESSOR OF MENTAL AND NERVOUS DISEASES IN THE NEW YORK POLYCLINIC.

THE treatment of so grave a disorder as epilepsy is a subject which may well claim the attention of all medical men. The disease is a veritable scourge that leaves its indelible mark upon the victim, often attacking him at an early age, unfitting him for the serious work of life and blighting all the hopes dependent upon him. In view of the importance of the subject, it need not surprise us that the subject has come up for discussion so frequently before our learned societies; and no apology is needed, I believe, for continuing before this Academy a discussion which was conducted most ably only a few weeks ago before the American Surgical and Neurological Associations at Washington.

The brilliant achievements of American and European surgeons have given us the utmost confidence in the possibilities of cerebral surgery, and, with the increasing knowledge of neurologists in localizing accurately the site of disease in the brain, there would seem to be no good reason why the results of cerebral surgery should not equal those in abdominal surgery. But, unfortunately for the patient and for us, the complicated structure of the brain makes cerebral disease a very different affair from disease in or around the abdominal viscera. Sufficient allowance is not, as a rule, made for this difference, whence it follows that in the case of the surgical treatment of epilepsy much has been expected and but little has been realized. It seems wise to me, therefore, before we allow our hopes undue scope, that we should stop to inquire what we can expect from the surgical treatment of epilepsy.

To those who have not acquainted themselves with the literature of the subject a simple answer may occur. They may say: "Take the recorded cases, note the results, and make your inferences"; but in the case of the surgical treatment of epilepsy statistics are useless. A few successful cases have been reported, and even these with undue haste. Von Bergmann † and the latest author, Sahli, ‡ have given up the attempt to tabulate the results of operations upon epileptic patients. I started out on the same path a few months ago, but soon found it would be love's labors lost. In this matter of the cure of epilepsy after operation the memory of medical men is not as reliable as it fortunately is with regard to most other diseases. A distinguished surgeon stated recently before one association that he knew of a case of traumatic epilepsy in which the cure

was of ten years' duration, and before another society, a few days later, that the longest cure that he knew of was of three years' duration. But what of the innumerable failures? They have not been reported with the same candor and promptness with which most men have heralded their short-lived successes. And if the attacks are inhibited for a number of weeks or months, is even this temporary success to be put to the credit of the operation? As long ago as 1875 Maclaren \* insisted that epileptics were improved by any operation whether it be for cancer of the pelvic organs, for joint disease, or what not; and it is as likely as not that some of the supposed cures after ovariectomies may be accounted for in this way, though I am not willing to go to the extreme to which Dr. White, † of Philadelphia, has recently gone, in putting the improvement following trephining for traumatic epilepsy in the same category with the "curative effects of operations *per se*," simply because no gross organic changes were found in the organ so exposed.

I propose to answer the question embodied in the title of this paper by presenting to you the views I am forced to hold regarding the nature of the disorder which we attempt to cure, and by giving you the results of my own experience in the surgical treatment of epilepsy—an experience that I owe chiefly to the kind offices of Dr. Gerster and Dr. Wyeth, with whom I have been associated in fourteen cases of cerebral operation, ten of which were done for the relief of epilepsy.

Let me remind you that epilepsy is a symptom, not a disease; that it is often merely one of a number of symptoms pointing to organic disease of the brain—to tumor, hæmorrhage, abscess, or widespread meningitis and sclerosis. In other cases it is a direct or remote effect of traumatic injuries to the skull or brain. In addition to these we have cases of genuine epilepsy, so called. Some one has suggested that it would be better to call them cases of epilepsy from unknown cause, and our modesty should, I think, incline us to this latter view. For one, I find that I see relatively fewer cases of genuine epilepsy than I did in former years. On closer examination I have not infrequently found that the epilepsy had taken its start from a long-forgotten injury or accident; that it was in its earlier days associated with paralysis, the paralysis having left but the slightest traces, while the epilepsy has remained distinctly enough. Nor is it to be supposed that a true epilepsy—I do not mean single convulsive seizures—is a functional disease. In our ignorance we may call it so, but with the improved methods of examining cortical tissue I am confident that we shall before long be able to demonstrate its anatomical substratum. Two French authors have been leading the way in this inquiry. Marie, ‡ who goes to the extreme of denying hereditary epilepsy, claims that children may be born epileptics, but they have not been conceived as such. By which he implies that, as in the case of congenital cerebral palsies, some slight lesion has been estab-

lished during the intra-uterine period; that this lesion may be lost sight of, but the secondary degeneration following upon it is the cause of this supposed hereditary epilepsy. Féré\* has furnished strong evidence in favor of this view. He induced Chaslin † to examine five brains taken from epileptic subjects; in all of these brains the most careful microscopical examination revealed an increase of neuroglia tissue with the formation of small fibrils emanating from the spider cells of the neuroglia. Chaslin infers that this is a sort of gliomatous sclerosis, and that this sclerosis is to be found in epileptic brains of entirely normal macroscopical appearance.

I have led you into this discussion of the anatomy of so-called genuine epilepsy in order to have you associate in your minds the idea of secondary sclerosis of the cortex with epilepsy. This secondary sclerosis is the pivot upon which the entire question turns. I repeat that in cases of idiopathic epilepsy the initial causal lesion has not yet been determined; idiopathic cases have by common consent not been considered proper cases for operation; but we have learned to operate in cases of localized epilepsy—Jacksonian epilepsy—due to focal disease, whether of traumatic origin or not, and in these cases the focus of disease is present, and so is the secondary sclerosis. If years pass by before death ensues, the focal disease may be beyond recognition, but the secondary sclerosis can be and has been recognized. In early childhood the cortex suffers focal injuries which might well be called traumatic, if they were due to an external force; but, whatever the cause may have been, we have a meningeal hæmorrhage often enough; the clot resting upon the cortex may be absorbed, but it has given rise to a local change which extends by degrees until it finally leads to secondary changes in the form of a lobar sclerosis. Paralysis and epilepsy are the chief symptoms of this condition. Instead of a meningeal hæmorrhage due to difficulty during labor, imagine a traumatic hæmorrhage; disregard the ætiological differences and the two accidents will result in the same processes.

Let us push the argument one step further. Every one is familiar with the fact that the convulsive seizure of a localized type is due to an irritative lesion of the motor or sensory centers. The most familiar cases of localized epilepsy are those due to discharging lesions in the motor areas. It is well known, too, that convulsive movements of a thumb or an arm point to a discharging lesion in the center or centers representing these parts. Those parts only are capable of a discharging lesion which are not actually destroyed; if destroyed, we have absolute paralysis and not localized convulsive seizures. Does the diseased area contain within itself the irritating power, or is this irritation conveyed to it from other parts? As a tumor grows near a center, it irritates that center and causes convulsive seizures; as soon as it has displaced or destroyed the center, the formerly convulsed part becomes paralyzed. The injuries and morbid processes with which we are here concerned rarely lead to the destruction of a center; it is capable of discharging,

and the irritation it needs seems to me to be supplied by that secondary sclerosis of which it—the focal injury—has been the prime cause. Is there any clinical evidence that the secondary sclerosis plays this part? I shall be very much mistaken if it does not explain the very curious fact that in traumatic injuries and in the cortical diseases of early childhood the epilepsy does not, as a rule, develop for months and even years after the focal lesion has been established. It takes months, and even years, until a large amount of sclerosis is established. It is fortunate that focal injuries are not invariably followed by sclerosis; why it should develop in some cases and not in others it is difficult to say; the severity of the lesion is not the sole determining factor.

Some may maintain that, while this reasoning may apply to epilepsy following organic diseases, the sclerosis has not been actually demonstrated in cases of traumatic injuries. The fault is with the investigator. Bergmann\* reports the case of a man who had received a gunshot wound of the left parietal bone in 1870; he was operated upon and bone was removed. Two years later he had the first epileptic attack. These attacks continued for fourteen years; then Bergmann trephined over the scar. The patient did well for one month; after that he fell into the status epilepticus, in which he died. The author assures us that the wound had healed perfectly, and that the cortex and dura were entirely normal—macroscopically, it may be—but no microscopical examination was made. Inasmuch as some of the cases to be operated upon hereafter may die, it will be well to make a most careful histological examination of the cortex in such cases.

Returning to the practical bearing of these pathological studies, we infer that we have an initial focal lesion and a condition of secondary sclerosis to deal with. It is our plain duty, therefore, to prevent the development of secondary sclerosis if possible, or, if it has been developed, to neutralize its effects. The first part of our task is by far the more difficult. Not knowing as yet the exact conditions under which this sclerosis is developed, we can scarcely be expected to meet these conditions; but we can attempt to diminish the initial lesion and, if possible, to remove it. This is equivalent to a plea for early operations in traumatic and organic cases. How can we neutralize the effects of a well-established sclerosis? Shall we say by excising the diseased area? The method is rational enough, since we can not rid the brain of the sclerosis.

This method of excision has been applied by Horsley, † Keen, ‡ Bergmann, and others. The results have been satisfactory in some cases, disappointing in others. In spite of the removal of the center, the sclerosis has exerted its power through other channels, through other irritable centers. If the diseased center is the only irritable area, the result will probably be a good one; but we have no means of predicting whether or not this will be the case. And to make matters worse, excision of a center means loss of function. You may not cure the epilepsy, but you are

\* Féré. *Les épilepsies et les épileptiques*, Paris, 1890.

† Chaslin. *Semaine méd.*, 1889.

\* *Loc. cit.*, p. 160, second edition.

† *Brit. Med. Journal*, April, 1887.

‡ Keen. *Am. Jour. of the Med. Sciences*, October and November, 1888.

very apt to paralyze the convulsed part; but this function of the excised part is very apt to be assumed by other parts of the brain, particularly in young persons, and among older persons the patient, if left to make his choice, will prefer a local paralysis to a severe epilepsy.

The practical conclusions to be drawn from the foregoing are these:

1. In a given case of traumatic or organic lesion, operate as early as possible, to prevent the development of secondary sclerosis.

2. If you have not operated at the outset, the onset of epilepsy is a warning that secondary sclerosis has been established; by operation at this time you may avoid an increase of the trouble.

3. Excision of the diseased area is the only rational operation; if all other centers are not in an irritable condition, the operation may be thoroughly successful.

But if we can not easily cure epilepsy, we may improve the patient's condition by diminishing the number of attacks. What we can accomplish I propose to discuss in the second part of this paper. I refrain purposely from entering upon the subject of operative interference in cases of tumor or abscess of the brain, as the advisability of operating is governed by motives other than the cure of the epilepsy. Traumatic epilepsies will attract us first, and next I wish to enlist your interest in certain forms of epilepsy associated with infantile cerebral palsies. These latter diseases have been so generally overlooked that the epilepsy constituting one of the symptoms has rarely been recognized as a special form.

Traumatic cases call for immediate surgical interference. Whenever the skull has sustained a severe or even a moderate injury, a surgeon or the attending physician should do an exploratory operation to make sure that there is no depression of bone. As trepanation is not a very dangerous operation, it would be better to do this than to have the slightest doubt. I was pleased to note that Dr. Agnew\* insisted strongly on this point in his recent paper at Washington. Together with Dr. Wyeth, I had the privilege of seeing, only a few weeks ago, a robust individual who had sustained a fracture of the skull by falling from his wagon; he was picked up in an unconscious condition, and, with the exception of an occasional lucid moment, remained in a condition of stupor up to the time of the operation. There was no paralysis and no focal symptom of any sort. Yet during the exploratory examination a large fracture was found which extended well back from the coronal to the lambdoidal sutures, and running for a part of its course along the sagittal suture. A trephine opening was made to see whether there was any splintering of the inner table, or whether the dura had been lacerated. As far as we could see, no severe injury had been inflicted; and the good, but slow, recovery which the patient has made may possibly have come about in this special case without any operation. Yet these are the very cases which so often develop epilepsy from pressure of depressed bone; and it seems to me fully as important that the surgeon

should operate early to determine whether there is a depression as that he should defer operation until epileptic symptoms appear which may place the case beyond the possibility of surgical relief.

After the epilepsy following traumatic injury of the skull or of the brain has been developed, there is still hope that the epilepsy may, in a few instances, be inhibited by surgical methods. For ages past trepanation has been the classical operation in these cases. Wherever depressed bone presses upon any part of the cortex, or an old scar acts as a source of irritation, the removal of such bone or scar is clearly indicated; in many cases improvement, if not a cure, of the condition follows. We must seek an explanation, however, for the improvement which follows trepanation in many cases of traumatic epilepsy of long standing in which there is no old scar and no marked depression of bone. We will not explain this on the theory that any or every operation helps; we know, however, that adhesions between the brain and its coverings are apt to be formed, and that traumatic cysts are very frequent. The trephine opening may therefore relieve the increased pressure due to these morbid conditions. It will be well to enlarge the trephine opening and to make it as ample as the conditions will permit. To show you how much or how little may be accomplished by mere trepanation, allow me to present the very condensed histories of a few cases of traumatic epilepsy. The full histories I hope to publish in due course of time, in conjunction with the surgeons who have done the operations.

CASE I.—Boy, aged sixteen years, from Madison, Wisconsin; no hereditary history. At the age of eighteen months fell out of a first-story window; since that time epileptic attacks of great severity, with occasional intervals of freedom from attacks. These generally begin in the right arm and extend to the leg and face; often they become general. Loss of consciousness in all attacks. I referred him to Dr. Gerster. Operated upon February 23, 1891. The skull was trephined over the arm area, which was proved to have been exposed by the electric test; the trephine opening extended so as to expose the greater part of arm and leg centers. Attacks set in two days after the operation and have continued with old-time severity. Result, no improvement. The father would not consent to a second operation.

CASE II—Young man, aged twenty years; works on his father's farm in New Jersey. At the age of twelve years was pushed backward over the pole of a wagon, striking, according to account, on the back of his head; was unconscious for a few minutes, but went to work. A week later the first general epileptic attacks; these attacks had recurred at varying intervals for two or three years. For the past three years the boy had attacks of typical Jacksonian epilepsy, in which the muscles about the right half of the mouth only were convulsed. I had occasion to see several such attacks. These minor attacks would occur many times a day. This series would be interrupted by an occasional severer attack of localized convulsions, ending up in general convulsions, loss of consciousness, etc. The boy, who is a fairly bright lad, desired the operation. This was done February 13, 1891, by Dr. Gerster. As demonstrated by the faradaic stimulation over the exposed area, the trephine opening had been laid exactly over the center representing, according to Horsley,\* the upper face and angle

\* Agnew. *University Med. Magazine*, 1891.

\* Horsley. *Am. Jour. of the Med. Sciences*, 1887, vol. i.

of the mouth. Adhesions were found under the button of bone which was removed. Good recovery, but attacks set in within a week after operation, and in these attacks the eyelids were convulsed, showing a slight extension of the focal lesion. A few weeks later the attacks were as of old in every respect. "No improvement whatever," so the boy reported to me eight months after the operation.

Somewhat better success has followed upon operation in two cases of sensory epilepsy of traumatic origin; as they are rare forms of epilepsy, I wish to refer to them briefly in this connection.

CASE III.—J. D., aged eight years. When seven months old fell upon the left side of the head; at eleven months began to have epileptic convulsions; twitchings usually began in the right arm and leg, and the mouth would be drawn to the left side. After the age of five years these attacks disappeared. Since last March the boy has had similar attacks; but with the onset of these attacks it was noticed that the ear began to discharge. The convulsive attacks were regularly preceded by auræ, in which he would either perceive a very foul odor or else imagine a steam-car close upon him. He would close the window to keep out the noise, and at once fall into a convulsion. The attacks would be more frequent whenever the discharge from the ear ceased. About one such attack occurred every week before operation.

The mastoid region was not painful, but everything pointed to mastoid trouble, and hence I sent him to Dr. Gerster for operation. On August 14th Dr. Gerster chiseled through the mastoid process into the middle ear and removed several sequestra; no pus. The wound healed quickly. The boy has had but one attack in two months, and is far less irritable and brighter than before.\* It is interesting to note that with the onset of this ear trouble the old epileptic tendency due to traumatism had been revived.

CASE IV.—A man, aged thirty years, of alcoholic habits, at the age of ten years was struck by a stone on the back and side of the head. Four years later he began to have general epileptic convulsions. These continued regularly; every two weeks he would have two or three attacks in a single day. Patient has become stupid and irritable; has left lateral hemianopsia. Operation, July 24th, by Dr. Gerster. Removal of occipital scar; external plate found to be depressed; this was removed with chisel. After dura was exposed and adhesions were cut away, the opening in the occipital bone was enlarged to the size of a silver dollar. The wound did well. Sixteen days after operation three epileptic attacks occurred; they were followed by transitory delusions of persecution, from which he soon recovered. He was discharged on August 15th, and had no attack until October 1st, after taking a large amount of liquor for the relief of pain. The result may be designated as a marked improvement. The hemianopsia has remained unaltered.

This is an epilepsy starting from one of the sensory areas of the brain, but whether the patient actually had a visual aura he is too stupid to state.

Our own experience in this matter is not unlike that of other physicians. Horsley, Bergmann, Park, Keen, and others have not fared much better.

In the search after better methods, Horsley's suggestion, in case of focal lesion to remove the entire diseased center, met with general favor. With the aid of our present methods of determining centers, and particularly if we

allow the result of faradaic stimulation of an exposed area to be our chief guide, we can very accurately determine the extent of the area to be removed, and I have satisfied myself that this can be done before the dura is opened. But, as I have intimated before, even the excision of diseased centers is not an unmixed good. First of all, it often fails. Attacks have returned after such operation in the cases of Bergmann, Park,\* and Keen. In one of Park's cases the contents of the cyst were emptied, but the cyst was not removed. Horsley's first case has been the only very positive success, no attacks having occurred for twenty-two months after operation.†

Rational as this method seems to be, there are reasons for its failure. The entire center may not have been removed; the paralysis of the convulsed part has been thought by Keen and others to be proof of the fact that the entire center has been removed. Then, again, if an arm center has been the actual focus of disease, the neighboring face or leg center may, in the course of years, have attained a sufficient degree of irritability to become the discharging center, and, furthermore, the existing sclerosis will help to advance this or other centers to the dignity of a discharging center, if they have not already acquired this unfortunate function.

Another serious feature of this excision operation, and indeed of all cerebral operations, is the possibility that the operation itself may lead to the formation of cicatricial tissue in or around the cortex, which may do more damage than the initial lesion. Yet, from what I have seen of the condition of brains years after an operation, I believe this danger from new cicatricial tissue to be quite slight.

Granting the entire success of the operation in question, you have at best in many cases substituted a paralysis for an epilepsy. In the case of an arm or face center, most patients would consent, and prefer the paralysis to their epileptic seizures. Few would care to have their leg centers excised, and to wait until some vicarious center may give them power to walk; and I doubt whether in Case IV, which I reported above, the patient or my own conscience would have permitted me to remove one visual center. Excision of a center, while it promises relief in a few well-selected cases, is not so much of a divine inspiration as it appears to some to be. Let us prevent traumatic epilepsy as far as in our power lies; it will be easier to prevent it than to cure it.

I consider it my duty to call your attention to the epilepsy associated with the cerebral palsies of children. In a paper ‡ published last year it was shown that forty-four per cent. of all cases of infantile cerebral palsies develop epilepsy, and I have stated that there could be but little doubt that, of all cases of ordinary epilepsy, a very fair proportion were developed in connection with infantile palsies. This view has been accepted by later writers. I have seen at least half a dozen cases of epilepsy within the past year

\* Park. *N. Y. Med. Jour.*, November, 1888.

† I can not find any later reference to this case. Other cases have been reported, but before a sufficient period of time had elapsed.

‡ Sachs and Peterson. *Journal of Nervous and Mental Disease*, May, 1899.

\* A second operation was done about two months later, since which time the boy has been free from attacks.

which were supposed to be cases of idiopathic epilepsy, but which, when examined carefully, revealed the traces of an old hemiplegia. Nor are the pathological conditions underlying these palsies properly recognized.

One case of Horsley's, a boy four years of age, with right hemiplegia, who had as many as thirteen or fourteen attacks per day, is a case in point. Dr. William A. Hammond\* some time ago reported the case of a girl of twenty, afflicted with an old hemiplegia, in whose brain he found a large cyst which was evidently the leavings of a former hæmorrhage, and Case V of Dr. Keen's† latest paper is not merely a case of defective development, but one of infantile cerebral hemiplegia with epilepsy and idiocy. I would not call attention to this class of cases if we did not find among them the only cases of non-traumatic epilepsy which demand surgical interference.

These palsies come on either in the intra-uterine period or early in life. The initial lesion in the acquired cases is generally a hæmorrhage, thrombosis, or embolism, and this focus of disease leads in many cases with rather surprising rapidity to the development of secondary sclerosis throughout the cortex. In fully ninety-five per cent. of all these cases the lesion is in or upon the cortex. The lesion—a hæmorrhage or softening, say—is very apt to be strictly limited to one or more areas. It need not, therefore, surprise us that typical Jacksonian epilepsy is found in some of these cases, or that we find scars and cysts and sclerosis just as we do in the traumatic cases.

The three cases of this class which I shall refer to were operated upon during the past year—two of them by Dr. Wyeth and one by Dr. Gerster. The histories are briefly as follows:

CASE V.—L. C., male, aged six years. Onset of disease at the age of five years with right hemiplegia and convulsions of a Jacksonian type which have been repeated every week since, finally increasing to as many as five daily; athetoid movements of right hand; is irritable and bad-tempered. Operation was done December 29, 1890. A large opening was made in the skull over the motor arm area of left hemisphere and enlarged from this; adhesions to skull broken up. No attacks for six weeks after operation, and none for several months after leaving the hospital. I have not heard from the boy in fully three months.

CASE VI.—A girl, aged sixteen, who has had right hemiplegia and epilepsy since early childhood: epileptic attacks very frequent and affecting paralyzed part exclusively. Dr. Wyeth operated upon the girl in the Polyclinic Hospital, exposing, by the method which I must leave to him to explain, the entire left motor area. In this area I determined by the use of the faradaic current the exact arm center. The dura was opened in semicircular fashion, but, as the entire area seemed normal, we did not at the time excise any part of it. The dura was closed, and the wound healed nicely; she was free from attacks for at least five months.

CASE VII has been by far the most interesting.‡ I was asked by Dr. Wyeth to see A. H. G., aged thirty-two, who had applied to him for the relief of his epilepsy. The history showed that the epilepsy had been developed at the age of two years, and

that with the epilepsy a complete left hemiplegia appeared. On examining the patient this hemiplegia was evident enough, and this, taken in conjunction with the history of unilateral attacks, led me to look for a focal lesion—a hæmorrhage probably—which, from the nature of the attacks, I thought likely to be most marked in the arm center. Dr. Wyeth trephined over this site, enlarged the opening, cut open the dura, and then exposed the discoloration and thickening of the pia which was adherent to the cortex beneath. A number of incisions were made into the cortex at this point, breaking up old adhesions, and lessening the increased tension at this point. The patient did well after the operation. On the second day the paretic arm was paralyzed, but after the lapse of a few days it was no worse than before the operation, while the epileptic convulsions, which had appeared at least once a week before the operation, did not occur until six months after the operation. The further course of this epilepsy will have to show whether any permanent improvement has been gained.

Simple trepanation seems to be more successful in these epilepsies associated with infantile cerebral palsies than in the traumatic forms, probably because of the still greater frequency of cysts in these diseases than in the traumatic epilepsies. The early recognition of these troubles is of great importance; and the question naturally arises whether we can diagnosticate the lesion with sufficient accuracy to encourage the surgeon to operate at an early day before secondary degeneration is established. I believe this will be possible in many cases, but the disease sets in frequently at a very tender age at which cerebral operations are but poorly tolerated; moreover, the epilepsy, although a probable sequel, is still a remote contingency; the paralysis represents the reality, and parents will be most apt to tell the physician to care for the present only, more particularly if looking to the future means a possible increase of the paralysis. As soon as epileptic symptoms appear, the paralysis has the value of a focal symptom; the centers should be exposed, and if not removed, they should at least be treated in accordance with the special indications of the case. In children, excision of a center is a less serious affair than in the adult, for in the former other parts of the cortex are capable to a greater degree of assuming the functions of the destroyed part. I am confident that, if these cases of infantile cerebral palsies are more generally recognized, and if we succeed in checking the tendency to epilepsy in them, the total number of epileptics will be noticeably diminished. If the surgical treatment of epilepsy be of any value at all, it is in view of the foregoing not to be restricted to the traumatic forms, but let it be applied also to those epilepsies which are associated with the cerebral palsies of childhood.

In conclusion, I would say that, under favorable conditions and by the methods described in this paper, the surgeon may be able to cure a few cases of epilepsy. He will be able to improve many, but surgeons and neurologists should in future make an earnest effort to *prevent* epilepsy.

**Ichthyol in Small-pox.**—"A solution of ichthyol, five or ten per cent., has recently been used with much success as a local application in small-pox, in the pustular stage of the eruption. The solution being painted over the pustules two to four times a day was found to hasten the drying up, check extensive suppuration, and prevent pitting."—*British and Colonial Druggist.*

‡ This case has been referred to in the author's paper on the Pathology of Infantile Cerebral Palsies, this journal, May 2, 1891.

## THE MANAGEMENT AND CARE OF PATIENTS WITH HEMIPLEGIA RESULTING FROM CEREBRAL HÆMORRHAGE.\*

BY WILLIAM M. LESZYNSKY, M. D.,  
LECTURER ON MENTAL AND NERVOUS DISEASES  
AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL, ETC.

IN discussing this subject, we must accept the term "hemiplegia" (paralysis of one side of the body) as indicating the predominant clinical manifestation of a disease, and not descriptive of the pathological process itself. In other words, to speak of hemiplegia as a disease would be at variance with our knowledge of its pathology and in opposition to the modern principles of nomenclature. In the vast majority of instances it is symptomatic of the rupture of an intracranial blood-vessel. This condition, which occurs suddenly and places the individual *hors de combat*, is essentially due to disease of the arterial system. It is merely supererogatory for me to mention that hemiplegia may result from other causes, such as cerebral embolism or thrombosis, or meningeal hæmorrhage, or from a tumor involving the intracranial portion of the motor tract, or from a unilateral lesion in the upper cervical portion of the spinal cord. I shall therefore confine my remarks to hemiplegia in the adult as a result of cerebral hæmorrhage.

The hæmorrhage is far more apt to occur in or near one of the corpora striata than in any other part of the brain. The point of selection is most frequently one of the lenticulo-striate arteries which has developed miliary aneurysms. All trustworthy observers are agreed that morbid changes in the arterial walls precede their rupture, although there are differences of opinion as to the character of such changes.

The extremities which are affected are always those on the side opposite to the lesion in the brain. This depends on the anatomical fact, so well known to you all, that the motor columns decussate in the anterior pyramids of the medulla. Thus, any unilateral affection of the nervous centers situated above the decussation of the pyramids, if it causes paralysis at all, invariably causes paralysis of the opposite side. Those movements which are performed in harmony by the two sides of the face or body remain unimpaired in hemiplegia.

Hemiplegia from a lesion of one side of the brain is not necessarily so complete as to present a maximum loss of power. Not infrequently the face escapes entirely.

Sometimes the leg can be moved perfectly, while the arm is completely paralyzed. Power is usually regained in the leg earlier than in the arm. A comprehensive and practical knowledge of general medicine is a *sine qua non* in the management of these cases. Its rational treatment presupposes a familiarity with its pathology. Obviously it is beyond the scope of this paper to enter at length into a technical and exhaustive description of cerebral hæmorrhage in its various phases.

Cerebral hæmorrhage is relatively frequent after the fortieth year and becomes more common as age advances. The

belief that it is of more common occurrence in men with short, thick necks and florid faces than in those who are of a different build is a popular fallacy. There is no such thing as an apoplectic constitution. Some families exhibit a predisposition to cerebral hæmorrhage. Hence it has been assumed that the disease is hereditary. It is only an indirect result of the inherited tendency to arterial degeneration.

Most writers speak of prodromic symptoms, and mention the following as premonitory signs of cerebral hæmorrhage: Headache, vertigo, tinnitus, or numbness in the hand or foot; facial paresis, coming on suddenly without spasm, and usually disappearing within a few hours or a few days. There may be loss of speech with this facial paresis, but more often defect of speech only. All of these symptoms are likely to arise where arterial degeneration exists, and may be due to local circulatory disturbances resulting either from gradual narrowing of the lumen of the vessel, or from thrombosis or embolism—or possibly from minute hæmorrhages; thus producing on the one hand a transient circumscribed anæmia, and on the other cerebral softening.

They may appear separately or variously combined, and although all of them may occur without being followed by an apoplectic attack, yet, in the old and middle-aged, especially when the arteries are degenerated, they should be regarded as warnings. The rupture has been known to occur without any precursory symptoms whatsoever.

Among the exciting causes of the attack may be mentioned excessive emotions, cold baths, and indulgence in stimulants, provided that the vessels are in the diseased condition, which seems to be a necessary antecedent of hæmorrhage; temporary obstruction to the return of venous blood from the brain, in such actions as coughing, sneezing, laughing, or straining at stool. It has been claimed that its direct effect must be small.

A number of instances have occurred under my observation, and no doubt many of you have seen similar cases, where the patient has been found in the closet either paralyzed or dead from cerebral hæmorrhage, undoubtedly as a result of straining at stool.

Cerebral hæmorrhage sometimes occurs first while the individual is making some violent effort or subjecting his vascular system to an excess of pressure. Sudden exposure to cold may increase the arterial tension by inducing extensive contraction of the cutaneous vessels. Cerebral hæmorrhage has also been known to occur during sleep, when the pressure in the cerebral vessels is supposed to be particularly low. I have often thought that possibly a change in the pressure might have been occasioned by an exciting dream.

Hemiplegia may occur suddenly without loss of consciousness. Then the recognition of the paralysis is simple both for the patient and the physician. During coma the diagnosis is frequently attended with difficulty owing to the general and complete muscular relaxation. The stertorous breathing and the concomitant facial paralysis are quite characteristic. In case the coma is only partial and the muscular resistance is feeble or lost upon one side, the diagnosis is clear.

\* Read before the Practitioners' Club, of Newark, New Jersey, January 4, 1892.

While the patient remains unconscious the prognosis is doubtful, as we are unable to determine the extent of the hæmorrhage. He may die comatose from shock, asthenia, or some complication.

Should consciousness be restored and the vital signs be maintained, the prognosis as to recovery from the paralysis depends upon a number of factors. Recovery from hemiplegia will occur from any kind of lesion, if it be a small one. If the patient begins to move the arm next day he is likely to get well altogether. We can not infer so much from early recovery of the leg, as this is very often not completely paralyzed at the outset, and we know that it frequently recovers when the arm remains much paralyzed. When rigidity of the limbs takes place no further improvement will follow. In this connection it will be of interest to call attention to some of the clinical signs of hemiplegia which heretofore have not been observed nor their value recognized.\* Corresponding to the well-known fact that in the facial paralysis accompanying hemiplegia the orbital portion of the nerve is usually unaffected, a similar phenomenon may be observed in the upper extremity in the fibers of the spinal accessory nerve. This nerve divides into two branches—one supplying the sterno-cleido-mastoid muscle, and the other the trapezius. As a rule, the branch to the sterno-cleido-mastoid escapes, while that supplying the trapezius is paralyzed. The latter paralysis manifests itself in the drooping of the shoulder while at rest. The paralysis in the lower extremity, which is usually neither complete nor permanent, also shows several characteristic peculiarities, which explains the fact that walking is still possible even in severe cases.

In such patients, while in the supine position, one can demonstrate that active elevation of the extended leg to a certain height can still be accomplished, although feebly. The dorsal flexion of the ankle joint is nearly or completely abolished, but plantar flexion can be performed with considerable force. In the prone position the flexors of the knee joint are nearly or completely paralyzed, while the extensors show a well-marked or almost normal strength. *Therefore in hemiplegia the muscles which are especially important in locomotion are the ones that are the least affected.*

During the early stage the clothing should be carefully removed, and all jarring of the head or body should be avoided. A ligature about the extremities close to the trunk will prove serviceable in diminishing the volume of blood in the internal organs, thus relieving the intravascular pressure and hastening the formation of the clot. This procedure is most likely to prove efficacious where the symptoms are indicative of a large hæmorrhage, or in those cases where there is an apparent tendency to an extension of the hæmorrhage.

Absolute rest in bed should be enjoined, no matter whether the attack be very mild or severe in character.

In case unconsciousness is present and lasts more than a few hours, the bladder should be relieved by the catheter. If there is reason to believe that there is an accumulation of fæces, five or ten grains of calomel or two drops of ero-

ton oil should be placed on the tongue, or an enema may be given. Whenever there is serious difficulty in swallowing, the administration of food by the mouth should be forbidden, on account of the danger of its entrance into the larynx. A day or two without much nourishment will do very little harm. If it is thought desirable, rectal alimentation may be resorted to. Further details in the management of this stage will suggest themselves according to indications.

There is neither clinical nor experimental evidence to prove that we possess any drugs whose administration will hasten the absorption of the extravasated blood or relieve the patient of his paralysis. As we can not remove the clot or directly hasten its absorption, let us ascertain what we can do for our patient. Before he is able to leave the bed much can be done by careful management and close attention to details to prevent unnecessary complications.

A good nurse or an intelligent attendant will prove quite an acquisition. Bed-sores over the sacrum and over the heels are not essential features of the malady, but are usually the result of carelessness and neglect.

The position of the patient must be frequently changed, and, either by a water-bed or by various mechanical devices, the points that are subjected to pressure must be protected.

In addition to these measures, it has been my custom to use a mixture containing two drachms of the oxide of zinc to the ounce of alcohol. The skin that shows any redness is painted daily with this preparation. As the alcohol evaporates, a thin coating of zinc remains on the surface. In rare cases the formation over the buttocks of a so-called bed-sore, which is due to trophic changes, may occur, despite the most careful vigilance. A few days after the attack, all joints of the paralyzed limbs should be daily subjected to gentle passive motion, in order to prevent the development of ankylosis. This is more likely to occur in the shoulder joint, and may also be classified among the avoidable complications. Electricity, in the form of the induced current, should not be used until from four to six weeks after the onset of the attack. The strength of the current applied to the paralyzed limbs should be just sufficient to produce slight but evident muscular contractions. The applications are to be made every alternate day, the entire *séance* lasting from ten to fifteen minutes. Faradization keeps up the nutrition of the paralyzed muscles and improves the condition of the peripheral circulation. The same may, however, be accomplished by suitable massage.

In view of the clinical fact that the extensors in the upper extremity and the flexors in the lower extremity are the muscles usually paralyzed, our electrical or manual manipulation should be directed in greater part to these groups of muscles. These applications will be of service while we are waiting for compensatory restitution of function. They prove useful as an artificial exercise.

In the presence of contracture which generally develops later, much can occasionally be accomplished by the use of galvanism applied to the brain and the peripheral nerves. The *anode* is placed over the parietal eminence on the same side as the lesion, and the *cathode* over the trunks of the nerves which supply the rigid muscles. The current is

\* Wernicke. *Berlin. klin. Wochenschrift*, 1889, No. 45.

gradually increased by the use of a rheostat, until the patient receives from three to six milliampères, the *séance* lasting from three to five minutes. Any sudden interruption in the circuit, either by removal of electrodes or by rapid increase or diminution of the current strength, should be carefully avoided, or sudden vertigo and other unpleasant symptoms may supervene. We must constantly bear in mind that central nerve fibers that have been torn across or broken up in any part of their course do not undergo regeneration, and that motility can not be restored in those parts which receive no motor impulses. We must not, therefore, delude ourselves in the belief that we can cure a hemiplegia. The most potent remedy that we possess is a combination of the "essence of patience" and the "tincture of time."

A partial restoration of function will take place in spite of all methods of medication instituted with the object of curing the paralysis. Here is where the *vis medicatrix nature* comes to our aid. Hence our efforts must be concentrated with a view to the prevention of another attack. This constitutes the most important element in the rational management of these cases. Nature can not be trusted in this instance.

It may be asked, Upon what grounds are we enabled to infer a predisposition to cerebral hæmorrhage?

1. From the history of a previous attack.
2. From the constitutional state which induces arterial degeneration—*i. e.*, senility, chronic nephritis, rheumatism, gout, syphilis, lead-poisoning, etc., often accompanied by cardiac hypertrophy.

3. From the presence of arterial degeneration itself, as manifested in the radial and temporal arteries by their rigidity and tortuosity. These evidences of degeneration are extremely suggestive, but are not proof positive of a similar condition of the cerebral blood-vessels. As a matter of fact, a number of cases are on record where post-mortem examination and careful microscopical investigation have shown normal cerebral vessels coexisting with degenerated temporal and radial arteries. On the other hand, the presence of retinal hæmorrhages furnishes an indication of considerable value. They are significant, inasmuch as they point to a state in which cerebral hæmorrhage is likely to occur. Some recent writer has referred to a varicose condition of the sublingual vessels as being one of the signs of arterial degeneration that is highly suggestive of a similar state in the brain. I have been unable to confirm this statement.

4. From the presence of high arterial tension, as determined by the radial pulse.

These are questions which demand immediate investigation. In all cases of cerebral hæmorrhage the condition of the arteries (statical, as atheroma; dynamical, as degrees of tension) is a matter of first importance. Too much stress can not be laid upon this point. We should never fail to examine the urine and satisfy ourselves as to the integrity of the heart and kidneys. In fact, every organ in the body should be examined.

Granting that the cause of the arterial degeneration is to a great extent irremediable, let us devote our attention

to the avoidance of exciting causes of the rupture. Every patient should be repeatedly impressed with the possible danger to which he exposes himself while straining at stool. He must be taught to avoid all additional causes that have been previously enumerated. Sneezing or coughing should be controlled or modified. Anything that is likely to produce a sudden increase of arterial tension should be scrupulously avoided.

In conjunction with the foregoing, the general plan of treatment which will be found appropriate in most cases would be to regulate the diet to suit the individual case; to reduce the quantity of nitrogenized food (if it had been used in excess); to keep the bowels free; to diminish high arterial tension by the use of salines or mercurials, or nitroglycerin, the nitrites, etc.; to administer antisiphilitic remedies when necessary. There is no proof that the use of strychnine, hypophosphites, or other so-called "nerve remedies" directly influences the paralysis. They should be restricted to those cases in which they are indicated for improving the general health.

I have thus briefly outlined what seems to me to be the proper method to be adopted in the management of an unfortunate class of cases that taxes the resources of the physician to the utmost.

Much of our success in averting another attack will depend upon the co-operation, self-denial, and self-control of our patient.

61 EAST SEVENTY-FIFTH STREET.

## ORIGIN AND RESTRICTION OF TUBERCULOSIS.\*

BY CHARLES G. CURRIER, M. D.

FROM an enormous number of experiments upon animals and from somewhat fewer than a hundred reported cases of accidental inoculation upon human beings, it is regarded as proved that the bacilli of tuberculosis, which are exceedingly numerous in the sputa and other excretions from foci of the disease, tend to cause tuberculosis whenever these characteristic germs in a highly vitalized form enter the system in sufficiently large numbers.

Primary affections of the lungs by these bacilli are oftener observed in autopsies than primary tubercular disease of any other part of the body. It has, further, been observed that cases of lung tuberculosis have arisen among some of the animals and human beings that have happened to be exposed to breathing in air containing among its dust particles those produced by the drying and pulverizing of tuberculous sputa. The fact that fatal tuberculosis resulted in such cases caused the extensive adoption of the generalizations enounced by Cornet; and, by the zeal of neophytes, the theory became almost universal that all the cases of tuberculosis that occurred were due to the inhalation of dried sputum, and that the "heredity" and "predisposition" of former years were obsolete and obstructive terms. Holding that the inhalation of the harmful bacillus was the sole

\* Read in a discussion at the New York Academy of Medicine, January 21, 1892.

important factor, although he appears to be modifying his views as with the years more complete and careful observations bring facts in refutation, Cornet even declares that "we daily are able to see that even the most robust people, apparently in the best of health, become the victims of the tubercle-bacilli infection."

Summarizing the observations made in two hundred and twenty-one autopsies of tuberculous cases, Grawitz, formerly Virchow's assistant, reported one hundred and fifty-two cases as primary in the lungs, nine as primary in the digestive tract, three arising from external wounds, and the original entrance of the infection was doubtful in the other cases. (*Deutsch. militärärztl. Zeitschr.*, 1889, Heft 10, Ref.) Then some of the many cases where animals were experimentally fed with tuberculous meat and milk resulted in intestinal infection. But such facts had been observed years before the characteristic bacilli were recognized. Leudet (*Gaz. hebdom.*, 1890, No. 9), reviewing many cases among married people in the better circles of society, states (like Brehmer and many others) that it is exceedingly rare for tubercular infection to pass from one spouse to the other. Schwarz and numerous others adduce the facts of long and extensive hospital experiences to show that hospital attendants are not so prone to the affection as Cornet assumed, and Haupt (*Med. Revue*, 1890, No. 1), gathering the statistics of two hundred and seventy-five female nurses encountering tuberculosis in a general experience, found that during twelve years only two of these nurses had manifested the symptoms of the disease. In this country, comprehensive investigations of nursing statistics made with similar care are not at hand. We, who have seen many cases in the homes of the poor before any care was paid to adequate disinfection, can not, so far as I learn, recall much evidence of the disease being communicated from one to another of those living in the unhealthy abodes of our lowest classes.

But, aside from the lack of positive evidence to prove the extremist views, there are further facts to negative or modify the postulates. Thus Prausnitz (*Archiv f. Hygiene*, 1891, p. 192) reports negative results when inoculating animals with dust taken from the floor of railway compartments in through trains carrying consumptives for many hours on the long journey through Bavaria. Kustermann (*Münch. med. Woch.*, Nov. 10, 1891, p. 796) reports wholly negative results from collecting dust from the walls and floors of the Munich prison hospital, and then inoculating this dust into animals.

Happily the element of contagion, even if existing on the clothes, the skin, and in all the secretions, soon loses its vitality under the conditions most prevalent. Koch has said that when exposed to daylight and the oxygen of the air, the tubercle bacilli present in dust form are liable to die in from a few hours to a few days.

Although the temptation is ever present to use a "royal road" for learning about the origin of the disease and, by assuming the inhalation theory as explaining all cases, to consider other explanations as unwarranted, it must be insisted that the inhalation theory accounts for only a portion of the cases, and that, after all, heredity seems a very potent source, as evidenced by the common-sense experience of

clinicians and statistical observers, as well as by bacteriologists of the highest standing, such as Professor Baumgarten (see *Deutsche med. Wochenschrift*, Oct. 13, 1891) and others, who are thoroughly conversant with the extensive literature of the subject and acquainted with all the progress and changes of the decade. An infant seems quite as liable to inhale the bacteria of exsiccated sputum as an adult is, and then to develop tuberculosis of the lungs if the inhalation theory is adequate to account for all cases; but we have the clinical fact presented us that the lungs do not develop tuberculosis in infants as often as in adult life, yet the glands, bones, and joints are relatively very often affected without any evidence that the infection arose primarily in the subject through inhalation of bacteria. These considerations, together with the occurrence of cases of foetal tuberculosis (Birch-Hirschfeld and Rindfleisch, *Münchener med. Wochenschrift*, 1890, p. 768), and the demonstrations, by comparative biologists, of the presence of bacteria in ova, as well as the established fact that "structurally healthy testicles of tuberculous subjects can have bacilli detectable in their spermatozoa"—all of these considerations warrant the conclusion that tuberculosis may be inherited. That is, the most potent factor in the causation of tuberculosis can, in foetal cases, be conveyed from a parent or parents immediately to the unborn child.

To explain later developments, whether manifested in the lungs, or in the bones, joints, glands, or elsewhere, the assumption of heredity seems more adequate than the inhalation theory, particularly because in childhood the lung manifestations are decidedly in the minority, even if we do not include the considerable percentage (twelve) of latent tuberculosis reported by Bollinger and others who have made numerous autopsies of children.

Even lung tuberculosis in adults is explicable in many cases by this modernized doctrine of heredity quite as well as by the inhalation theory. We know so very little of the life history of the tubercle bacillus under such conditions of nutrition and environment as these parasites find in various organs of the human body, that we are quite unable to fix any limit as the time beyond which they can not remain in a state of latency, endowed with a capacity for resuming their most virulent activity. Atmospheric, telluric, and other external influences which are not yet fully understood, together with internal conditions that are as yet beyond our complete comprehension, may, so to speak, arouse the bacilli from this latency, and they then may develop with varying rapidity and harmfulness. Under circumstances that foster the vitality of these micro-organisms, serious and progressive disease may result. With other factors at work, the morbid manifestation may be very slight. Whatever the extent of the morbid process, the pernicious activity of the bacilli may be followed by their more or less total destruction if the disease be arrested, or they may again become dormant. Those that chance to be in a less suitable region, as in the muscles, develop less readily than when in a more favorable organ, as, for instance, in the lung.

It is probable that in the earliest period of life the great formative and vital energy of the body-cells offers a

high degree of obstacle to the activity of the tubercle bacilli, which survive, if at all, usually in a latent state, unless exceptionally virulent or exceedingly numerous. If from any cause the system weakens and thus loses its power to restrain the destructive activity, the disease process ensues with its varying phases.

Since, then, the inhalation theory explains the origin of only a portion of the cases of tuberculosis, we must base our hygienic warnings upon the broadest understanding and further recognize that the terrible disease arises also from other sources than from sputa; yet we should keep constantly in mind the probable danger of infection coming from dried sputa and from other excretions.

The zeal of research in this field has led to reports that the harmful bacilli are detectable even in the sweat and on the clothing of "consumptives," and, even if what Mattei and Spillheim have said in this connection does not prove to be verified by further tests, we should admit the probability that scientifically prosecuted cleanliness is a valuable safeguard against the extension of the scourge.

In view of the part that heredity plays in the propagation of tuberculosis, we must, in combating the disease, direct unremitting attention toward increasing the sum total of the vital forces of the patient, and all climatological, pharmacodynamic, and other means should be employed which give the system added power to resist or destroy the parasites. Not the least important aid to the patient is the maintenance of a high degree of vitality before the bacilli have been enabled to make sufficient inroad to become detectable through the usual physical and other symptoms.

Our duty, then, is to remain both conservative and progressive, to utilize the valuable truths evolved from the tireless laboratory researches of the present, and yet to respect the unquestionable facts established by clinical observers.

The methods by which to prevent the passage of the infection of tuberculosis from the lungs of one person to the lungs of another have been indicated by the various commissions and health officials here and in the cities of Europe. Scientific cleanliness is the beginning and the end of all effectual means. Heat is apparently the most reliable disinfectant. The germ-destroying value of fresh air does not seem to be appreciated as generally as it should be.

In order to influence the masses, sanitary instructions for the restriction of tuberculosis should be very brief, although detailed explanations of the facts, the methods, and the reasons for these may be given at length.

For the guidance of the many, then, we may formulate the knowledge of to-day in this regard as follows:

Keep clean. Avoid unclean places and avoid unclean and diseased people.

Do not spit on the floor or on the ground, and do not allow others to do so.

Expectorated matter loses its harmfulness when burned.

Clothing and other articles used by "consumptives" can be sterilized by exposure to the heat of boiling water for at least fifteen minutes.

It is safest to use milk, water, and other foods only after they have been well cooked.

Abundant fresh air is a valuable purifier.

## ON THE BENIGN COURSE OF ABSCESS IN POTT'S DISEASE UNDER EFFICIENT MECHANICAL TREATMENT.\*

BY NEWTON M. SHAFFER, M. D.,

ATTENDING SURGEON IN CHARGE OF  
THE NEW YORK ORTHOPÆDIC DISPENSARY AND HOSPITAL.

My early medical education was received under the direction of one of the most conservative medical men I have ever met—viz., the late Dr. James Knight, the founder of the New York Society for the Relief of the Ruptured and Crippled. Some of the present members of the American Orthopædic Association also received their first orthopædic training under the same auspices, and with them I can recall the feeling of criticism—not to say ridicule—with which we regarded Dr. Knight's treatment of "cold" abscesses in Pott's disease and in hip-joint disease. Those of our number who passed several years under his preceptorship have had, since we left the institution, ample opportunities to compare his method with the various operative methods; and I think it is a safe thing to say that we are not, even at this date, entirely in accord upon the question of the treatment of chronic tubercular abscess of the spine or major joints.

My own experience has been a varied one. When I left the institution I felt that I had escaped from an unwarrantable restraint, and, with the enthusiasm of my years, I went to the opposite extreme and fell into the error of accepting Sayre's adaptation of the old proverb, "An empty house is better than a bad tenant," a saying, I am assured, that has done much harm as applied to tubercular abscess in chronic articular disease. Experience has taught me that if a qualification could be added to Sayre's dictum, it would express the real state of the case. And this qualification is, "when one can be sure that the tenant will behave well under eviction, or that the tenant will not damage the whole house before he leaves."

I feel that surgeons generally stand as a unit on the subject of the surgical treatment of *acute* abscess; and if the *chronic* abscess in tubercular disease resembled the acute abscess in its more important particulars, we should not hear the animated discussion that always follows the introduction of the question of the treatment of abscesses arising from tubercular joint disease. And I think it is correct to assume that we are all too apt to regard "abscess" in its generic sense rather than in its pathological sense—that we are too apt to regard a fluctuating tumor, containing the products of a chronic, infectious disease, as a something to be got rid of at almost any cost—ignoring the fact that the contents of a tubercular abscess differ in many important respects from the contents of an abscess due to an acute, non-tubercular lesion. How many of us would hesitate about the propriety of opening a well-marked acute perityphlitic abscess? How many of us would deliberately open a chronic intrapelvic abscess due to an active and progressive tubercular disease of the dorso-lumbar spine?

The conservatism of Dr. Knight amounted practically to

\* Revised remarks delivered at the fifth annual meeting of the American Orthopædic Association.

a surgical nihilism. The extremists who would open every tubercular abscess connected with an actively diseased spine or joint are, I think, as much in error as those who ignore the indications which point to surgical interference. Unfortunately, with all our discussions on this subject, we have no statistics to demonstrate either the weakness or the strength of either position; but I feel safe in stating that more recoveries occur under the plan of non-interference than under the one which indiscriminately applies the knife to every chronic articular abscess.

My own results—after I adopted the plan of opening every chronic abscess—were not so satisfactory as those which followed non-interference. It is true that at that time the antiseptic method of Lister was not available, and the tubercular bacillus had not been discovered by Koch. After the antiseptic method was introduced I followed it very closely, but still I found my results in chronic abscess of joint disease were not satisfactory. It seemed to me that in opening a tubercular abscess from Pott's disease, for example, we were treating a "symptom" rather than the disease; that we were tapping a reservoir, and paying but little attention to its source; and that we were in too much haste to give exit to the so-called "pus," which kept on flowing from the source, notwithstanding our external antiseptic dressings. It seemed that high temperature would frequently develop, notwithstanding the gauze and protective and irrigation and drainage, and that repair, as a rule, was delayed rather than promoted by our efforts to find a short route to recovery.

After an experience among many cases and many methods, I came gradually to adopt a course which appeared to me to have a rational foundation. I attempted to insure as perfect a mechanical protection as possible to the diseased joint or spine and to maintain the general health in every available way, hoping that the actual disease might cease before the abscess opened (and this proved to be the case on many occasions), or to await the occurrence of either severe local or important general symptoms, due to the abscess itself, before I resorted to incision, etc. After I adopted this plan, I found to my surprise that many abscesses entirely disappeared; that some became quiescent or encysted; that few, if any, gave rise to trouble; that those which opened spontaneously almost uniformly did well; and that my results were more satisfactory and more permanent.

My experience is that tubercular abscesses in Pott's disease, as well as in the abscesses of the chronic tubercular lesions of the major articulations, pursue a very benign course under efficient mechanical protection to the diseased articulation, and that we too often resort to the use of the knife. If the disease is cured, then the abscess becomes a local affair and we may treat it as such, though it then usually disappears spontaneously.

Among the many cases I could submit to illustrate this position I cite the following:

Master S. W., aged eight years, consulted me on March 4, 1887, bringing a letter of introduction from Dr. Weir Mitchell. The patient had Pott's disease of the spine, involving the eleventh and twelfth dorsal vertebrae. There was a slight kyphosis,

which had evidently been progressing for over a year, but which had been unnoticed until it was discovered by Dr. Mitchell. The patient was pale and thin and in a generally bad condition, but gave a good hereditary history. The prominent feature of his case was the presence of three large abscesses—one in the pelvic cavity, another in the gluteal region, and a third on the inner aspect of the thigh—all on the left side. Fluctuation could be detected between the femoral and pelvic abscesses. The gluteal abscess seemed not to be connected with the others. Both the gluteal and femoral abscesses were very large, the former being especially prominent, while the latter increased the circumference of the thigh three inches over the measurement of the thigh of the unaffected side. The pelvic abscess extended nearly to the free border of the ribs. The patient had only a slight rise of temperature, the daily evening temperature averaging 99.6°, the morning temperature averaging 98.2°, for a period of over a month during which the record was kept. The analysis of the urine showed nothing abnormal, and all the vital organs were in good condition.

An antero-posterior support (a modified Taylor's) was carefully adjusted, though at first it seemed difficult, on account of the gluteal abscess, which was so large and extended so high up that it interfered with the hip band of the apparatus. Special provision being made for this, the apparatus was adjusted and the patient was closely watched. He went to his home in May after ten weeks of careful treatment, during which there was a very perceptible decrease in the size of all the abscesses, and in July, 1889, they had wholly disappeared. Careful attention was paid during treatment to the general health and to the climatic surroundings of the patient. He did not spend one day in bed on account of his spinal disease during the entire treatment. I saw the patient during the present summer (1891), and he is well and strong and as active as many boys of his age. As he was so active, I advised that a very light apparatus be worn as a matter of precaution simply, though I have not regarded the patient as being under treatment since May, 1890. The curvature has not increased.

On November 5, 1890, Miss J. B., of Brooklyn, aged ten years, consulted me, bringing a letter of introduction from Dr. Samuel T. Hubbard. The patient had Pott's disease of the first and second lumbar vertebrae, with abscesses very much like those existing in the case just related—viz., large intrapelvic, gluteal, and femoral abscesses—the two last named being especially large and prominent. The patient did not have any rise of temperature above the normal. The antero-posterior spinal apparatus was applied, and the patient was brought to me from Brooklyn every week. Constitutional remedies were used, and the patient was instructed to go out of doors every pleasant day. At the end of two months there was a perceptible decrease in the size of all the abscesses, and at this date (September, 1891) fluctuation can not be detected at any point, and the patient is in remarkably good health. The apparatus is still worn, and the patient is still under professional observation. The kyphosis has not increased.

I have related the histories of these two cases, among many others that might be cited, because the abscesses were very large; and because they may be regarded as extreme cases. Simple abscesses in Pott's disease do not occasion me any anxiety, and I have not a single case to record in private practice where, after deciding to pursue the policy of non-interference, I have had occasion to regret it. The cases that have been the most troublesome and the most unfortunate are those in which the abscesses have been

opened when the indications for so doing were not plainly evident.

This is only the experience of a single individual. I submit it as a contribution to the study of a very important subject.

## BROMAMIDE:

### A NEW ANTIPYRETIC AND ANTINEURALGIC REMEDY.

*A Preliminary Report of an  
Experimental Research into its Therapeutic Value.*

By AUGUSTUS CAILLÉ, M. D.,

PROFESSOR OF DISEASES OF CHILDREN,  
NEW YORK POST-GRADUATE MEDICAL SCHOOL;  
CHAIRMAN OF PEDIATRIC SECTION, NEW YORK ACADEMY OF MEDICINE;  
VISITING PHYSICIAN TO THE GERMAN HOSPITAL AND DISPENSARY, NEW YORK,  
ETC.

This drug is described by its discoverers, Messrs. F. H. Fischedick and Charles E. Koechling, of New York city, as a new bromine compound of the anilide group containing seventy-five per cent. of bromine ( $C_6H_2Br_3NH.HBr$ ).

It is in the form of colorless, needle-shaped crystals, nearly odorless and tasteless, insoluble in hot or cold water, slightly soluble in cold alcohol, and soluble in sixteen parts of boiling alcohol. Chloroform, ether, and the fixed oils dissolve it, but it is insoluble in benzine. Its action toward litmus paper is neutral. It is a very stable compound, not being affected by any of the ordinary reagents. It melts at  $243^\circ F.$ , and volatilizes at  $310^\circ F.$  without change, subliming in beautiful feathery crystals.

Bromamide was first given to dogs and rabbits, in doses of 2 grammes (30 grains), without noticeable deleterious influence and without affecting the composition of the blood in these animals. The administration of from 0.6 to 1 gramme (10 to 15 grains) to healthy adults was followed by a slowing of the pulse *without sweating*. The administration of 0.06 to 0.2 gramme (1 to 3 grains) to children from one to three years of age was accomplished without untoward symptoms.

The experiments as to the therapeutic properties of bromamide were carried on at the German Hospital from June 1 to November 1, 1891, and suffered embarrassing interruption in the beginning of the experimental term, in consequence of the resignation of the entire house staff. Bromamide was administered in the following class of cases: Typhoid fever, acute articular rheumatism, chronic rheumatic arthritis, chronic nephritis, acute fibrinous pneumonia, rheumatic fever with acute endocarditis, general and localized dropsy due to hepatic, renal, or cardiac disease, and diverse forms of neuralgia; and special attention was given to a possible antipyretic, diuretic, diaphoretic, antineuralgic, and sedative action of the drug.

CASE I.—C. P., aged twenty-four; typhoid fever, third week.

June 4, 1891.—Bromamide, 10 grains (0.6). Temperature: 5 P. M.,  $104.2^\circ$ ; 6 P. M.,  $104^\circ$ ; 7 P. M.,  $103.3^\circ$ ; 8 P. M.,  $102.9^\circ$ ; 9 P. M. (bromamide 10 grains),  $102.9^\circ$ ; 10 P. M.,  $102.7^\circ$ ; 11 P. M.,  $102.5^\circ$ ; 12 M.,  $103.3^\circ$ .

7th and 8th.—Ten grains of bromamide at 5 P. M., with results as above stated.

9th.—Bromamid, 10 grains. Temperature: 5 P. M.,  $103.4^\circ$ ; 6 P. M.,  $103.3^\circ$ ; 7 P. M.,  $103.3^\circ$ ; 8 P. M.,  $100.9^\circ$ ; 9 P. M.,  $100.6^\circ$ ; 10 P. M.,  $101^\circ$ ; 11 P. M.,  $100.6^\circ$ ; 12 M.,  $100.6^\circ$ .

10th.—Temperature: 1 A. M.,  $100.8^\circ$ ; 2 A. M.,  $101.1^\circ$ ; 3 A. M.,  $101.1^\circ$ ; 4 A. M.,  $101.4^\circ$ .

Bromamide was not again administered after June 10th, as the temperature continued to remain low. In this case the pulse and respiration were not materially influenced, and no sweating or evil effects were observed.

CASE II.—F. B., aged twenty-six; attacks of severe cardialgia, with a history of vomiting of blood (ulcus ventriculi?); 0.6 (10 grains) of bromamide promptly relieved the pain on four different occasions. When administered the fifth time it had no effect, and other treatment was adopted.

CASE III.—G. H., aged twenty-three; acute articular rheumatism, acute endocarditis, anasarca.

June 6th.—At 8 P. M., 0.6 bromamide (10 grains). Temperature,  $103.5^\circ F.$  On the following morning the temperature was still high, and three doses of bromamide (10 grains each) were administered during the day, at intervals of three hours. The evening temperature, June 7th, was  $99^\circ F.$ , the temperature declining uniformly. Six hours after the last administration of bromamide this patient was seized with severe cramps in the abdomen, which radiated around both sides of the body and down the front of the thighs; the features were tightly drawn, indicating excruciating pain, the face became somewhat cyanotic, the pulse rapid, weak, and intermittent, the legs were flexed upon the abdomen, the skin became cold and clammy, a condition of general collapse being imminent. After several hours of energetic stimulation the patient rallied and recovered. In the opinion of the writer, the severe colic and subsequent collapse in this patient, with acute and extensive endocardial inflammation, were not brought about by the administration of bromamide.

CASE IV.—F. G., chronic nephritis; general anasarca; responding poorly to usual treatment.

August 4 to 10, 1891.—Bromamide, 10 grains morning and afternoon each day. Urine: On the 4th, 2,900 grammes; 5th, 3,000 grammes; 6th, 2,500 grammes; 7th, 2,500 grammes; 8th, 2,000 grammes; 9th, 1,600 grammes; 10th, 1,600 grammes.

The temperature in the above case was normal, the pulse rather slow. No change was observed in the constituents of the urine, and the diuretic powers of bromamid in this case were *nil*.

CASE V.—C. P., aged twenty-six; typhoid fever; admitted June 4th. Patient received 10 grains each of calomel and jalap after admission, and an enema daily, and no other medicine.

June 6th.—Temperature, 9 A. M.,  $104.2^\circ F.$ ; 10 grains of bromamide. The temperature fell in two hours to  $102.9^\circ$ . Temperature, 6 P. M.,  $103^\circ$ ; 10 grains of bromamide.

7th.—Temperature, 9 A. M.,  $103^\circ$ ; no fall. Temperature, 6 P. M.,  $103.6^\circ$ ; 10 grains of bromamide.

8th.—Temperature, 9 A. M.,  $101.8^\circ$ ; 6 P. M.,  $104.2^\circ$ ; 10 grains of bromamide. Temperature, 10 P. M.,  $100.6^\circ$ .

The amount of urine passed was not satisfactorily recorded.

CASE VI.—S. L., aged thirty-three; chronic nephritis, without œdema.

October 20, 1891.—Passed 1,100 grammes urine in twenty-four hours. Received 10 grains (0.6) of bromamide daily.

Urine.—October 21st, 1,800 grammes; 22d, 1,600 grammes; 23d, 1,800 grammes; 24th, 1,800 grammes; 25th, 1,300 grammes; 26th, 1,300 grammes; 27th, 1,900 grammes. No marked diuretic action was observed. Patient complained of no unpleasant symptoms.

CASE VII.—O. S., aged twenty-three, servant. Diagnosis, typhoid fever.

September 17th.—Temperature, 4 P. M.,  $103^\circ F.$ , 1.0 of bromamide; 8 P. M.,  $104.1^\circ$ .

18th.—Temperature, 4 P. M.,  $103.2^\circ$ , 1.0 of bromamide; 8 P. M.,  $103.8^\circ$ .

19th.—Temperature, 4 P. M., 102·8°, 0·6 of bromamide; 8 P. M., 103·8°.

In this case the administration of bromamide was not followed by a reduction of temperature, and its further use was discontinued.

CASE VIII.—G. H., aged twenty-three; confectioner. Diagnosis, acute articular rheumatism. Admitted May 26, 1891, and treated for four months with all traditional and recognized methods of treatment without deriving more than temporary benefit, and with frequent and irregular periods of exacerbation.

September 24th.—Temperature, 103·6°; pulse, 120; respiration, 24; urine, 1,300. Bromamide, two doses, each 0·6, at 9 A. M. and 8 P. M.

25th.—Temperature, 2 A. M., 100·8°; 4 A. M., 99·2°; 6 A. M., 98·8°; 8 A. M., 100°; at noon, 99°; 4 P. M., 100°; 8 P. M., 99°. Urine, 1,850 grammes.

26th.—Two doses of bromamide, each 0·6. Temperature, 4 A. M., 99°; 8 A. M., 99°; 4 P. M., 99·6°; 8 P. M., 100°. Patient rather stupid but sleepless.

27th.—Bromamide, 0·6, morning and evening. Temperature throughout the day below 100°, except at 4 P. M., when it was 101·8°. Fair appetite; open bowels; urine, 1,950 grammes in twenty-four hours.

28th.—Two doses of bromamide. Temperature, 8 A. M., 99·3°; 4 P. M., 102°; 8 P. M., 99°. Urine, 2,200 grammes.

29th.—Bromamide, two doses. Temperature as on previous day. Patient states that he considers himself improving.

October 3d.—The temperature has remained normal for the past three days, and the administration of bromamide is discontinued. The patient remained under observation for a week more, during which time the temperature was normal, except on one occasion, when it was 101°.

CASE IX.—Child, aged three; acute fibrinous pneumonia, first stage. In this case the morning and evening temperatures were both high (above 104° F.).

October 18, 1891.—Temperature, 8 A. M., 104·3°, 0·2 (3 grains) of bromamide; 11 A. M., 102·5°; 6 P. M., 104°, 0·2 of bromamide; 9 P. M., 102·8°.

On the following day the same amount of bromamide was given, with about the same result; the case terminating favorably in the usual time, without further medication.

Bromamide was administered symptomatically in a number of cases of neuralgia from various causes.

1. Compression myelitis, with intercostal neuralgia. No beneficial effect from 10 to 20 grains of bromamide.

2. Premenstrual headache, 15 grains of bromamide; marked relief in two hours.

3. Reflex hemicrania from carious tooth; 15 grains of bromamide; relief in three hours.

It will be seen from a perusal of the foregoing that the trials thus far made are encouraging, and may warrant further experiments, especially in other forms of disease.

Bromamide has the power of reducing the temperature in most cases of febrile disease from 1° to 2·5° F., without the excessive sweating as produced by other antipyretic drugs. It has, according to the above-recorded experiments, no pronounced diuretic action, and it is, so far as could be ascertained, free from unpleasant symptoms as regards the digestive tract. The lancinating abdominal pains noticed in several of the severe forms of disease can not fairly be attributed to the use of bromamide, because such phenomena were never observed when the drug was administered to healthy subjects.

Bromamide can safely be given in 10- to 15-grain doses (0·6 to 1) several times a day, as an antipyretic and anti-neuralgic to adults, and in doses of from 1 to 5 grains (0·06 to 0·3) to children. It may be given in capsule, in wafer, or dry upon the tongue, or suspended in a fluid.

In conclusion, I take pleasure in expressing my indebtedness to Dr. Kurth, Dr. Inglis, and Dr. Moscovich, of the house staff, for valuable assistance in securing these notes.

## OBSERVATIONS ON PARALYSIS OF THE EXTERNAL TENSORS OF THE VOCAL BANDS.\*

BY GEORGE W. MAJOR, M. D.

MONTREAL.

On the 3d day of January, 1891, G. G., aged twenty-five years, a bartender by calling, applied at the clinic for diseases of the throat and nose, Montreal General Hospital, for treatment for loss of voice. He stated that on the 2d of January he had driven a fast horse for ten miles in the face of a very cold wind with his throat unprotected. At the time he experienced some discomfort; this was succeeded by slight pain referred to the front of the larynx. On rising on the morning following the drive he was unable to utter a sound. On palpation of the throat, a tender spot was discovered over the region occupied by the crico-thyroid muscles. It was also noticed that, on attempted phonation, these muscles failed to contract. There were no other sensitive areas, nor was there evidence of swelling anywhere in the neck. The patient was in the enjoyment of his usual health, and no indication of constitutional disturbance existed. The voice was muffled, coarse, and in monotone. The breathing was noisy and, if judged by the peculiar sound produced on inspiration and expiration alike, might be considered difficult, but there was a total absence of dyspnoea. The man himself claimed that his respiration was quite satisfactory. A laryngoscopic examination revealed the fact that the free edges of the vocal bands presented the wavy outline that is considered to be characteristic of paralysis of the crico-thyroid muscles—the external tensors of the vocal bands. On expiration, the vocal bands appeared to be convex on their upper surface, and on inspiration somewhat concave. On phonation, the vocal bands seemed flaccid and relaxed, and the points of contact between the free edges were not constant. The larynx was otherwise in a normal state. On the 20th of January the patient, whose habits of life were most irregular, contracted a severe cold, and he was admitted into the wards of the hospital. There was now some tenderness over the whole thyroid gland, but no apparent swelling; the tonsils and pharynx were red, swollen, and painful. By the third day the thyroid gland was very much increased in size and tender. Breathing was also difficult when recumbent; the laryngeal image, however, underwent no alteration in configuration. The swelling had almost entirely disappeared in four or five days under the use of linseed poultices and other suitable treatment, and the difficult breathing had ceased. The patient was discharged on the 1st of February, eleven days after admission, cured. The vocal condition was still unchanged. As he left for England, the subsequent history is unknown.

Paralysis of the external tensors is a rare affection, and therefore worthy of being recorded when met with in prac-

\* Read before the American Laryngological Association at its thirteenth annual congress.

tice. It is very exceptional indeed to encounter a case where the recognized symptoms were so very well marked as in this instance.

The wavy outline of the glottis, the convexity of the upper surface of the vocal bands on expiration and on phonation, the concavity on inspiration, the unstableness of the points of contact of the free margins of the vocal bands at different intervals, and the flaccid and relaxed appearance of the vocal bands—were all well-developed features. The contraction of the crico-thyroid muscles on phonation when the cricoid cartilage was elevated in front, and which can be readily felt in the average throat, was entirely absent.

The occurrence of the acute inflammation of the entire thyroid gland during the period of paresis (without altering the configuration of the image) was also an unusual and interesting complication. The freedom from dyspnoea and the presence of noisy breathing during the paralysis are points worthy of note. The difficulty of respiration, which supervened when the inflammation of the thyroid gland was at its height without modification of the laryngeal image, is presumptive of tracheal rather than nerve pressure.

**The West End Medical Society.**—At the annual meeting, held on the 6th inst., officers for the ensuing year were elected as follows: I. R. F. J. Bowles, president; Dr. G. W. Leonard, vice-president; Dr. F. Spencer Halsey, recording secretary; Dr. H. G. Myers, corresponding secretary; Dr. S. V. Ten Eyck, treasurer; and Dr. C. N. Dowd, pathologist.

**The Hospital Graduates' Club.**—At the next meeting, to be held at the Arena, on Thursday evening, the 25th inst., Dr. Parker will read a paper on The Surgery of the Gall Bladder.

**The Pan-American Medical Congress.**—At the recent meeting of the Medical Society of the State of New York a committee was appointed to co-operate in promoting the interests of the congress. The committee consists of Dr. A. Walter Suiter, Dr. A. Van Derveer, Dr. James D. Spencer, Dr. Seneca D. Powell, Dr. W. W. Potter, Dr. D. B. St. John Roosa, and Dr. John O. Roe.

**A Case of Coloboma of the Optic Nerve with Simultaneous Melanoma of the Ciliary Process.**—“Dr. Talko publishes in the *Przeglad Lekarski* the case of a boy of five years old who, from his birth, had been suffering from considerable impairment of sight. He discovered in both eyes a coloboma without a vestige of the hyaloid, and a melanoma of the ciliary process as well, the first case of the kind he had seen in his ophthalmic practice of thirty years. No such case has, as far as he knows, ever been mentioned in medical literature. Dr. Talko is not certain if the embryonic deformity of the ciliary processes is merely a complication of the coloboma, or whether it may be found independently of other deformities of the eyeball. The case, as the first of its kind, certainly deserves to be recorded.”—*Lancet*.

**Thilanine.**—“This is a new modification of lanolin, obtained by Liebel by the action of sulphur on lanolin, and which is stated to be a definite compound. Dr. Sadfeld, of Berlin, has experimented with it in his dermatological practice, and reports very favorably on its action in various affections. It gives rise to no irritation and allays all itching, and is said to be destined to supersede Hebra's ointment in dermatological work.”—*British and Colonial Druggist*.

**The Melting Point of a Mixture of Salicylic Acid and Acetanilide,** says the *British and Colonial Druggist*, has been found by H. Prusse (*Pharm. Ztg.*) to be lower than that of either of the separate ingredients, the greatest difference being produced in a mixture of one molecule of acetanilide and half a molecule of salicylic acid. There is believed to be no chemical change, and that the bodies act upon each other merely as solvents.

NEW YORK, SATURDAY, FEBRUARY 20, 1892.

THE CARTWRIGHT LECTURES.

PROFESSOR OSBORN gave the first lecture of the series on Friday evening of last week. It was devoted to the evolution of the human body by development and by degeneration. The fundamental facts that structures on which an increased functional demand is made to correspond with changes in the surroundings of the race undergo a development that fits them for new or heightened action, and that parts which have become almost or altogether unnecessary or useless gradually disappear by degeneration—these facts were illustrated by many striking and interesting examples. And these were both kept clearly distinguished from mere anomalies.

Among the instances of development mentioned were the following: The elaboration of the spines of the cervical vertebrae, with the division of the upper ones in the higher races; the increase of the antero-posterior curves of the vertebral column in the same races as compared with the nearly straight spine of the negro; the encroachment of the pelvic on the dorso-lumbar and thoracic portions of the vertebral column, as exemplified in the increasing tendency of the twelfth dorsal vertebra to become the first sacral, and of the twelfth rib to disappear; the increased size of the cranium and the later closure of its sutures in the higher races, as contrasted with the earlier closure of the sutures of the face in those races and of the cranial sutures in the negro; the widening of the base of the scapula in the higher races, associated by Gegenbaur with the development of the scapulo-humeral muscles and the greater play of the humerus as a prehensile organ; the perfection of the hand in its adaptability to precise work, as contrasted with the fitness only for seizing objects in remote times, when the thumb was incapable of being opposed to the fingers; the progressive divergence of the female pelvis from that of the male in type; and the increased development of the great toe, so that the heel and the ball of the great toe constitute practically the points of support in standing, walking, etc., with the consequent eversion of the foot.

As examples of evolution by degeneration Professor Osborn mentioned, among others, the diminished size of the jaw in the modern man, that of the Englishman of the period having been found by Collins to be one ninth smaller than that of the ancient Briton, and about half as large as that of the aboriginal Australian, as compared with the size of the skull; the disappearance of the third incisor tooth and the impending disappearance of the wisdom tooth; the dwarfing of the outer portion of the foot, before alluded to, and especially the disappearance in many instances of the last phalanx of the little toe; and the tendency of the flexor hallucis longus to fuse with the flexor hallucis communis.

Professor Osborn's way of putting what he has to say might well serve as a model to most members of the medical profession. Although not himself a medical man, he shows great aptitude at turning his anatomical knowledge to account from the medical point of view. Some of his expressions are effective largely by virtue of their humor. The following are examples: "From the typical mammalian standpoint man is a degenerate animal; his senses are inferior in acuteness; his upright position, while giving him a superior aspect, entails many disadvantages, as recently enumerated by Clevenger, for the body is not fully adapted to it; his feet are not superior to those of many lower Eocene plantigrades; his teeth are mechanically far inferior to those of the domestic cat. In fact, if an unbiased comparative anatomist should reach this planet from Mars he could only pass favorable comment upon the perfection of the hand and the massive brain. Holding these trumps, man has been and now is discarding many useful structures. I refer especially to civilized man, who is more prodigal with his inheritance than the savage. By virtue of the hand and the brain he is, nevertheless, the best adapted and most cosmopolitan vertebrate." Referring to a compensatory readjustment of parts so that the nutrition of an entire region remains the same, to which process the term *metatrophism* was applied, he spoke of it as "the gerymander principle in nature." He mentioned the eighth rib as having been "recently floated from the sternum." It was putting it pithily when he said "structure lags far behind function in evolution."

We are glad to be able to say that Professor Osborn's audience was large and seemed to be appreciative.

### MINOR PARAGRAPHIS.

#### THE TREATMENT OF MALARIAL AFFECTIONS WITH METHYLENE BLUE.

THE recent experiments of Guttman and Ehrlich with methylene blue as a remedy in malarial diseases, employed on account of its property of coloring the *Hæmatozoon malariae*, have been repeated by Laveran, the discoverer of that organism. The former reports were favorable to the utility of the agent in such diseases. Laveran injected methylene blue under the skin of pigeons having hæmatozoa in their blood, but the organisms did not decrease in number and did not seem to take the color. He also gave from thirty to forty centigrammes a day to two patients having malarial disease, giving to one as much as 7.4 grammes (more than 110 grains). There were no particular hæmotic phenomena, and there was no diminution of the organisms; the fever returned at the usual hour, and, aside from the coloration of the urine, there was no effect from the administration of the drug. So it may be concluded that in this drug no new specific has been added to our resources.

#### TYPHUS IN NEW YORK.

THE recent importation of typhus into New York and its consequent dissemination through various parts of the country call for quite as vigorous measures as the New York Board of Health is carrying out. That these measures will result in keeping the disease within manageable limits we thoroughly believe. Therefore we see no reason for the public to apprehend a widespread epidemic. At all events, the community should under-

stand that typhus is not a disease that strikes down all sorts and conditions of men indiscriminately, but is confined to those whose surroundings are decidedly insanitary. Moreover, there is no danger of its spreading from one house to another, except through human intercourse; hence, the use of houses in various parts of the city for purposes of isolating patients involves no danger to persons living near such buildings.

#### RICORD'S EPITAPH.

IN an interesting address on Ricord delivered at the annual meeting of the *Société de chirurgie* by the secretary-general, M. Monod, which is published as a *feuilleton* in the *Union médicale*, we are told that M. Ricord had, long before his death, made careful preparations for his interment, and had written his own epitaph, which he often read to his friends, and with which he seemed to be pleased. The lines are as follows:

Aux portes de l'Éternité,  
Quand j'aurai fini ma carrière.  
S'il me reste un peu de poussière  
De cette triste humanité,  
Que le tombeau seul s'en empare;  
Que de mon âme se sépare  
Cette cause de mes douleurs;  
Car l'âme pure et sa matière  
Doit être un rayon de lumière  
Que ne troubleront plus les pleurs.

#### A NOVEL USE OF A BENZOINOL SOLUTION OF MENTHOL.

DR. ELIZABETH N. BRADLEY has sent us a brief note on the case of a patient, sixty-four years old, of a rheumatic diathesis, who had been suffering for several days from the pneumonic and cardiac complications of *la grippe*, when an attack of acute prolapsed hæmorrhoids ensued one night. The usual remedies having proved unavailing, either in alleviating the pain or in overcoming the spasm of the sphincter, it occurred to the doctor that spraying the hæmorrhoids with a benzoinol solution of menthol, which had proved very efficacious in controlling a paretic tendency of the laryngeal muscles in the same case, might so stimulate the muscular structure of the hæmorrhoidal veins as to accomplish a sufficient diminution in the volume of the piles to render them reducible. The spraying of the hæmorrhoids was followed almost instantaneously by a cessation of pain and by such a decrease in the volume of the tumors that their spontaneous reduction speedily ensued.

#### THE MARINE-HOSPITAL SERVICE.

THE *Annual Report of the Supervising Surgeon-General of the Marine-Hospital Service of the United States for the Fiscal Year 1891*, a volume of 354 octavo pages, comprises a well-arranged and satisfactory account of the operations of the service during the year, of much the same character as has been given in the reports for former years. The new Surgeon-General, Dr. Walter Wyman, has proved an efficient and acceptable officer, as was to be expected at the time of his promotion. In his own report he recommends measures for isolating persons affected with leprosy, but he does it temperately and without committing himself to the doctrine that the disease is contagious, merely remarking that where indifference is manifested as to the isolation of patients it slowly spreads.

#### THE OLDEST AMERICAN EX-HOSPITAL INTERNE

AT an annual meeting of the Hospital Graduates' Club, of New York, held two or three years ago, a letter from the late

Dr. Henry I. Bowditch, of Boston, was read, and the announcement was made that, so far as could be ascertained, Dr. Bowditch had "walked the hospitals" earlier than any other American physician then living, having been a house officer in the Massachusetts General Hospital in 1829. Dr. John L. Vandervoort, who for so many years was the librarian of the New York Hospital, and who died last summer, was an interne in that institution in 1832, and Dr. Benjamin W. McCready followed him in 1834. So far as we are able to ascertain, there is no American physician now living who antedates Dr. McCready as a hospital interne.

#### TUBERCULOSIS IN BUDAPEST.

THE *Deutsche Medizinisch-Zeitung* cites a statement of Professor Fodor's, in the *Pester medicinisch-chirurgische Presse*, No. 52, 1891, to the effect that the mortality from tubercular disease is relatively greater in Budapest than in any other large city in the world, the annual number of deaths being between 590 and 600 to each 100,000 inhabitants, while in Vienna it is between 540 and 550, and in London only between 180 and 190.

#### THE UNIVERSITY OF BUFFALO.

WE learn from the *Illustrated Buffalo Express* that work has been begun on a handsome and spacious new building for the School of Medicine, almost as large as that of the corresponding school in Columbia College. The Buffalo Medical College has for many years stood high among our American schools, and we are glad to note this evidence of prosperity.

#### ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending February 16, 1892:

DISEASES.	Week ending Feb. 9.		Week ending Feb. 16.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus.....	0	0	86	0
Typhoid fever.....	9	7	7	6
Scarlet fever.....	210	25	225	39
Cerebro-spinal meningitis....	2	1	0	1
Measles.....	132	13	204	10
Diphtheria.....	122	23	123	37
Small-pox.....	11	2	8	1
Erysipelas.....	0	0	4	0
Varicella.....	0	0	18	0
Pertussis.....	0	0	1	3

**Insanity in Paris.**—*Progrès médical* says that a book recently published by Dr. Paul Garnier, physician to the special infirmary of the *Préfecture de police*, shows that between the years 1872 and 1888 insanity increased about thirty per cent. in Paris.

#### Society Meetings for the Coming Week:

MONDAY, *February 22d*: Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

TUESDAY, *February 23d*: New York Academy of Medicine (Section in Laryngology and Rhinology); New York Dermatological Society (private); Buffalo Obstetrical Society; Boston Society of Medical Sciences (private).

WEDNESDAY, *February 24th*: New York Surgical Society; New York Pathological Society; American Microscopical Society of the City of New York; Metropolitan Medical Society (private); Auburn, N. Y., City Medical Association; Berkshire, Mass., District Medical Society (Pittsfield); Philadelphia County Medical Society.

THURSDAY, *February 25th*: New York Academy of Medicine (Section in Obstetrics and Gynecology); New York Orthopaedic Society;

Hospital Graduates' Club (New York); Brooklyn Pathological Society; Roxbury, Mass., Society for Medical Improvement (private).  
FRIDAY, *February 26th*: Yorkville Medical Association (private); New York Society of German Physicians; New York Clinical Society (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

SATURDAY, *February 27th*: New York Medical and Surgical Society (private).

### Proceedings of Societies.

#### MEDICAL SOCIETY OF THE STATE OF NEW YORK.

*Eighty-sixth Annual Meeting, held at Albany on Tuesday, Wednesday, and Thursday, February 2, 3, and 4, 1892.*

The President, Dr. A. WALTER SUITER, of Herkimer, in the Chair.

(Concluded from page 188.)

**Early High Amputation in Senile Gangrene.**—Dr. C. A. POWERS, of New York, reported a case in which he had amputated through the middle of the femur at the New York Cancer Hospital, for arterio-sclerotic gangrene in a man of sixty-seven years, whose gangrene had extended to the foot and lower leg. His patient died on the fourth day from hypostatic pneumonia, yet a post-mortem examination of the stump revealed firm, primary union, no pus, and no areas of malnutrition. The paper was in support of Mr. Jonathan Hutchinson's recommendation that when the gangrene had extended from the toes to the sole or dorsum of the foot immediate recourse (barring contra-indications) should be had to amputation above the knee, inasmuch as it was more than probable that a lower amputation would be followed by gangrene of the flaps and increased danger to life. Dr. Powers cited some twenty-five cases of Küster's, recently reported by Heidenhain, an analysis of which gave strong confirmation of the proposition that in order to obtain sound tissues one must amputate through the thigh.

In the discussion, Dr. WILLY MEYER, of New York, and Dr. HERMAN MYNTER, of Buffalo, cited personal cases showing the value of the procedure.

**Surgical Shock.**—Dr. J. H. PACKARD, of Philadelphia, read a paper thus entitled. Shock and collapse were said to be non-identical, though their phenomena were similar. Collapse might result from other causes than shock. The various definitions of shock were referred to and criticised. Shock always signified suddenness of occurrence. It might be followed by reaction and that in turn by collapse. The term shock had come into use less than sixty years ago, though the condition had been recognized for ages. In former times shock had been supposed to be peculiar to gunshot wounds. Since the general introduction of machinery and the development of railroads, with the injuries which attended such modern appliances, the cases in which shock occurred had multiplied. Delcasse wrote upon this subject in 1834, and denominated the condition *commotion*. Morris described the condition in 1867, and since that date the condition had been referred to by many writers. Shock was a very common accompaniment of burns, especially if they were of a severe character. The condition was evidently due to a depression of nerve force, and it was intensified in cases in which there was great loss of blood. The temperature was usually lowered in such cases, though it might rise several degrees when reaction occurred. Cases were recorded in which the temperature had fallen to as low a point as 80° F., and such cases were almost invariably fatal. The symptoms of

shock were sometimes apparent in cases in which anæsthesia was induced in patients with an abundance of food in the stomach. Emesis having occurred, the symptoms of shock would disappear. Undue exposure of a patient during an operation or the use of an abundance of water in irrigating a wound encouraged shock, and this fact taught that patients should be kept as warm as possible at such times. Delays in operating should be avoided as far as possible, no time being lost in demonstrating the steps which were taken. If irrigation was necessary, only hot water should be used. The propriety of operating in the presence of shock, as in the case of accidents, had long been questioned; such a procedure seemed to check or prevent reaction, and death was often the result. When the pulse became irregular and weak, the anæsthetic should be withheld. Alcohol was sometimes harmful as a means of relief in shock; it was also sometimes useful by its rapid diffusion. External heat was a valuable means of treatment, and morphine was indicated if severe pain was present.

Dr. A. VAN DERVEER, of Albany, called attention to the profound shock that frequently attended injuries from crushing weights, and said that injuries of this character were often followed by bad results. It was by no means necessary that the loss of blood should be great for profound shock to occur.

Dr. L. S. PILCHER, of Brooklyn, suggested the hypodermic injection of nitroglycerin, in doses of  $\frac{1}{100}$  of a grain every hour or two, as one of the efficient means of overcoming shock.

Dr. MYNTER did not think that shock was usually due to loss of blood. One of the operations which was most frequently attended by profound shock was linear craniectomy, especially if the operation was prolonged by operating on both sides of the cranium. The loss of blood in such cases was small, but the nerve injury was apparently serious.

Dr. R. F. WEIR, of New York, suggested the hypodermic use of strychnine, in  $\frac{1}{2}$ -of-a-grain doses, as a means of relieving shock, also nitroglycerin, in  $\frac{1}{2}$ -of-a-grain doses, and rectal enemas of hot water.

Dr. ROBERT T. MORRIS, of New York, suggested as means of treatment the inhalation of nitrite of amyl until there was flushing of the face, also the measures suggested by the previous speaker.

**A Discussion on the Surgical Management of Genito-urinary Calculus.**—Dr. J. D. BRYANT, of New York, discussed the question of diagnosis and the indications for surgical treatment of stone in the kidney. The condition and shape of the stone would depend on the state of the kidney at the time the formation was accomplished. The diagnosis of stone in the kidney was often very difficult, and even in cases in which the symptoms pointed almost unmistakably to that condition an operation sometimes failed to reveal its presence. Rough and irregular stones caused much more disturbance than smooth ones; they might even cause serious disorganization of the kidney and death, and yet be very small. The symptoms might be classified as suggestive and convincing, the former leading to a possible diagnosis, the latter pointing to the condition with greater probability. Such symptoms as renal or lumbar pain and vesical and urethral irritation were suggestive symptoms. Abnormalities in the constituents of the urine might exist and no stone be present. Such a symptom was, however, suggestive, and might, at a subsequent period, be convincing, the stone in the mean time having developed. The true condition was sometimes revealed by vesical irrigation and cystoscopy. Operative and exploratory treatment was to be advocated if the suggestive symptoms did not disappear.

Dr. L. A. STIMSON, of New York, discussed the question of the surgical treatment of stone in the kidney. The subject was a complex one. If the stone was large and the kidney not dis-

organized its removal by nephrotomy was indicated. If the kidney was severely diseased, nephrectomy should be performed. In some cases nephrectomy was required as a secondary operation. The operation could be performed by the extraperitoneal or the transperitoneal method, the former being preferable and usually performed. The kidney was reached by a longitudinal incision in the lumbar region which was met by a transverse one. The kidney being exposed, its pelvis was to be explored with a needle or with the finger. Entrance to the organ was to be effected by an incision through its pelvis, if possible, but, if this was impossible or impracticable, the incision must be made through the cortex. Not only should the interior of the organ be explored and all calculi removed, but the exploration should be carried as far as possible into the ureter. The wound should then be packed with gauze and drained. If the organ was to be removed, all manipulations of it should be made with as little force and violence as possible. Special care should be exercised in securing the pedicle. The artery might be ligated separately, or, if a mass ligature was used, it should be an elastic one.

Dr. ARTHUR T. CABOT, of Boston, discussed the question of stone in the ureter. Impaction of calculi within the ureter might be caused by irregularities in their contour. Impaction might be so firm as to cause serious injury to the ureter, the kidney, or both, or the stone might be dislodged by the pressure of the urine from behind. The pain caused by a stone in the ureter was a most important consideration, not only on account of its subjective influence, but also on account of its influence in determining a diagnosis. Thickening of the wall of the ureter was one of the conditions that might attend the presence of a calculus. The state of affairs being assured, it would next be of importance to find out the exact location of the offending body, and this was usually very difficult except in the lowermost portion of the ureter, where it could be palpated through the vagina or rectum. Palpation through the abdomen in very thin people would sometimes enable one to locate it as high as the brim of the pelvis or even higher. In other cases the location must be determined by an abdominal incision. The treatment of this condition was considered as preventive, non-operative, and operative. Operative procedures would be influenced by the question of the presence of stone in only one or in both kidneys, and it must be remembered that if there were a stone in one there often was a stone in the other also. If an operation was decided upon, it was very desirable that it should be performed without opening the peritoneum. The incision which should be made in the loin to reach the ureter followed an irregular line and was described. This incision would enable one to reach all but the lower three or four inches of the ureter. An anterior incision was not practicable for the removal of the calculus, though it might be useful in locating it. The posterior incision obviated the division of the peritoneum. The ureter having been reached and incised, and the stone removed, the wound could either be closed with fine silk or allowed to remain open and heal by granulation. The latter method was believed to be preferable.

Dr. EDWARD L. KEYES, of New York, discussed the question of stone in the bladder, and that of what special indications should govern a choice of operation as between lithotomy and lithotripsy. He remarked that the three modern procedures, litholapaxy, cystoscopy, and prostatectomy, had changed the course of the treatment of stone in the bladder. The size of the stone did not now affect the treatment, so far as the result was concerned, or perhaps it would be more correct to say that the smaller stones were better treated with the lithotrite, the larger ones with the knife. Lithotomy, in some respects, required more skill than lithotripsy, and yet it was not always easy to

grasp and crush a small stone without doing injury to the tissues of the bladder. The age of the patient was not now a matter of such consideration as formerly. Crushing could be performed upon persons of all ages, and it should be preferred as an operative procedure in all cases prior to the period of puberty. For persons in middle life the perineal section was frequently the preferable operation, especially if stricture of the urethra or cystitis was present. For cases in which the stone was sacculated the suprapubic operation was to be preferred. For old men with enlarged prostate the suprapubic operation was to be preferred, and the prostate might be operated upon at the same time.

Dr. L. B. BANGS, of New York, discussed the indications for choicing between suprapubic lithotomy and lithotripsy.

**Fibroid Disease of the Heart.**—Dr. A. L. LOOMIS, of New York, read a paper on this subject. Heart failure with pneumonia, resulting fatally, was frequently attributable to fibrosis. Changes in the coronary arteries, or anything which caused changes in the parenchyma of the heart, might precede fibrosis. Some of the causes that induced fibrosis were toxic changes in the blood, mechanical interference with nutrition, and traumatism of various kinds. The most important causes were those that interfered with cell nutrition and lowered the vital force. Toxic causes acted primarily upon the cardiac walls. The diagnosis of fibrosis of the heart could sometimes be made during life, and even in the early stages of the disease. The disease should be carefully distinguished from valvular disease. Irregularity of the heart's action was likely to occur early in the disease and to be permanent. The heart's action was feeble and intermittent, and palpitation was frequently complained of. Unusual efforts of all kinds would cause difficulty. Precordial anguish followed at a later stage of the disease. If the diagnosis was made early, the development of the disease might be prevented, or its progress delayed. The treatment would consist mainly in the regulation of the diet, exercise, and mode of life. All suitable means should be adopted to increase elimination and improve the nutrition. The best remedial agents were mercury and iodide of potassium in small doses. Digitalis and other drugs of similar character would do no good and might do harm.

**Dilatation and Drainage of the Uterus for Disease of the Endometrium.**—Dr. W. GILL WYLIE, of New York, read a paper thus entitled. Until recent years chronic endometritis had been supposed to be due principally to displacements of the uterus, especially antelexions, and the treatment had been adapted mainly to the straightening of the organ. This treatment had consisted in the use of pessaries and various forms of intra-uterine stems. Such measures were usually ineffective, because the principle of drainage was usually overlooked. The author's method of treatment consisted in divulsion of the uterine canal and the introduction of a grooved, hard rubber stem within the uterus, which allowed of a free escape of all secretions. The treatment of the uterine cavity should be based upon the same principle as the treatment of any other diseased cavity, and drainage was at the foundation of such treatment. The intra-uterine tube should be left in position for a week or, in some cases, for a longer period. If the disease proved obstinate and pointed to the existence of serious lesions in the tubes and ovaries, it might be necessary to remove the latter.

Dr. W. M. POLK, of New York, believed that drainage as a general principle was most important in the treatment of endometritis. If it was ignored, the uterus might retain products of decomposition and serious results ensue. He dissented from the statement that the uterus could not be dilated sufficiently in all cases to admit the introduction of a gauze tampon and retain it. He believed that antiseptic gauze was the best material for

an intra-uterine tampon. He also insisted that the dilatation of the uterus and introduction of the tampon should be performed under an anæsthetic. He believed that by means of the tampon a certain number of cases of pyosalpinx could be efficiently drained, and that in this way abdominal operations might sometimes be avoided.

Dr. MORDECAI PRICE, of Philadelphia, believed that dilatation, drainage, and packing of the uterus were all useless. In cases in which such measures were taken it would usually be found that pyosalpinx was the cause of the trouble, and the trouble could be relieved only by removing the cause.

Dr. JOSEPH PRICE, of Philadelphia, believed that indications for operations within the pelvis were pre-ent now which had not been present, at least to any considerable extent, ten or fifteen years ago. It was this condition of affairs which justified the pelvic surgery of to-day. He also was of the opinion that there had been an excess of uterine and intra-uterine treatment. Perhaps it was responsible for much of the existing pelvic disease. Sterility, for which much of the gynæcological treatment was given, was better treated in many instances by rest on the part of the woman and separation from her husband.

Dr. P. F. MUNDÉ, of New York, believed in the existence of chronic endometritis, and in certain well-recognized methods of treatment. It was not fair to assume, as some of the previous speakers had, that those who advocated intra-uterine treatment, and did so after extensive experience, were lacking in judgment. The speaker was an advocate of both the dilator and the curette, and he also sometimes used the gauze tampon and the intra-uterine stem. He was also in favor of astringent and caustic applications to the uterus on proper occasions. He sometimes used a fifty-per-cent. solution of chloride of zinc in the uterus after curetting.

Dr. H. J. BOLDT, of New York, was in favor of drainage of the uterus by means of the gauze tampon. If disease of the annexa was ever caused by gynæcological treatment, it was owing to want of care on the part of the one who administered the treatment.

Dr. JOSEPH HOFFMAN, of Philadelphia, believed that endometritis was usually due to some form of displacement, or was the consequence of a tear in the vaginal portion of the cervix. He objected to the use of caustics in the treatment of this disease, but was in favor of dilatation to a certain extent.

**Four Cases of Unioocular Blindness immediately following Injuries of the Skull.**—Dr. P. A. CALLAN, of New York, read a paper in which the cases were narrated and the principle was deduced that in these and similar cases blindness was caused by compression of the optic nerve at the foramen opticum.

**Methods of advancing the Internal Rectus for Divergent Strabismus.**—Dr. L. HOWE, of Buffalo, read a paper thus entitled. The methods heretofore in use were described and their defects pointed out. The author showed a forceps that he had devised for seizing the muscle after it and its opposing muscle had been divided. Keeping control of this muscle, preventing its retraction, would obviate one of the most annoying features of the operation. He also described a method of introducing the suture which would prevent their slipping, and also prevent the puckering of the muscle under the conjunctiva, which was sometimes a source of great annoyance to the patient. This plan was also designed to prevent over-correction of the strabismus, and was believed to be an improvement upon Prince's method.

**A Hip Splint** was shown by Dr. S. R. MORROW, of Albany. It was similar in construction to the Gibney and the Taylor-Davis splint, but very much lighter, the metallic portion being of aluminium. Its weight was about sixteen ounces; the other instruments weighed five or six pounds. This difference in

weight would offer a decided advantage to the delicate children who were usually the subjects of hip disease.

## NEW YORK ACADEMY OF MEDICINE.

SECTION IN ORTHOPÆDIO SURGERY.

*Meeting of January 15, 1892.*

Dr. SAMUEL KETCH in the Chair.

**The Disappearance of Large Psoas Abscesses.**—Dr. T. HALSTED MYERS presented a case of lumbar Pott's disease to illustrate the disappearance of very large psoas abscesses without material interference with the general health during the process. In this case, which had a strong family tendency to tuberculosis, the abscesses had appeared early, had gradually increased in size, but after an attack of measles it had become much larger, so as to fill both iliac fossæ and form pouches in both inguinal regions as large as a man's fist. At this time the liver had been slightly enlarged, but there never had been a trace of albumin in the urine. Eight months later, though still anæmic, the child had felt well, had had an excellent appetite, and the liver had regained its normal size. Absorption was rapidly progressing. At present the child had a temperature ranging between 98.4° and 99.6° F., and a few of the cervical glands were enlarged; but he played hard all day, had a good appetite, and felt well. The abscesses had almost entirely disappeared, and recovery seemed assured.

Dr. NEWTON M. SHAEFFER said that he had seen this case from time to time, and could testify to the large size of the abscesses. This case would certainly have been considered by some a fit one for operative interference, notwithstanding such an operation would necessarily have proved rather serious, on account of its extent. As usual under proper mechanical treatment, the abscesses had disappeared.

Dr. V. P. GIBNEY said that in connection with this subject he desired to report an instructive case. About fifteen years ago a boy had been brought from the West to the hospital with disease of the lumbar spine. The brace at that time in vogue at the hospital had been applied, and the child had done well for two or three years, when he had experienced some pain in the left thigh and a tumor had appeared in the left iliac fossa. The speaker had advised the systematic use of hot-water douches over the parts, and the result of this treatment had been considered at the time to be quite brilliant. He had only just learned the sequel of this patient's history. Shortly after the disappearance of the abscess from the iliac fossa, and while still wearing the spinal support, an elongated tumor had made its appearance in Scarpa's space, and had then burrowed down until it had nearly reached the inner condyle. There had been then some redness and tenderness, so the hot douches had been resumed, with the effect of causing an entire disappearance of the tumor. Nothing further had occurred until several years afterward, when, after a fall or strain of some kind, a large and tender tumor had made its appearance very suddenly on the outer side of the thigh, at the junction of the middle and upper thirds. This had been accompanied by pain and considerable constitutional disturbance, and a surgeon had incised the abscess, removed some bone detritus, and irrigated the cavity. Since then, although the sinuses had been washed out daily with bichloride-of-mercury solution, and afterward with peroxide of hydrogen, and then dressed with sublimate gauze, they had been discharging pretty constantly, and there had been occasional symptoms of sepsis. The remnant of the sac could still be felt in the iliac fossa. The tumor, which appeared on the outer side of the thigh, was probably nothing more than the old abscess deflected by the concussion of the fall. The speaker

said that he had narrated the history of this case because it was one of those in which the abscess had disappeared under what was considered to be good treatment, and yet he was not entirely satisfied with this treatment. He had seen many cases in which the abscess had disappeared in this way, and he was glad when this had occurred, but sometimes he could not help feeling that it might be better if he could, under thorough anti-sepsis, remove this pus by a surgical operation, and so relieve the patient from this constant menace.

**The Use of Iodoform in the Local Treatment of Strumous Joint Diseases.**—This was the title of a paper by Dr. J. D. BRYANT, who used the terms "strumous disease" and "tuberculous disease" synonymously. For practical purposes the products of tuberculous joint disease might be said to be located in the joint cavity and its lining membrane and in the circumarticular tissue associated with this membrane. The rice and melon-seed bodies in these diseased joints were often infected with the tuberculous agents. In the present paper the author excluded from consideration disease of the integument and of the immediate subcutaneous tissues. The preparations of iodoform which had been used by the author had been ten-per-cent. solutions with ether or glycerin. The ethereal solution was easily obtained in an aseptic condition, it flowed freely through needles of small caliber, and, by its rapid diffusibility, quickly deposited the iodoform upon the disease products. But this very property of rapid diffusibility made it objectionable on account of the liability of producing constitutional effects and because of the irritation produced by the fluid, which made the injections extremely painful and often gave rise to circumscribed abscesses. A solution of iodoform in sterilized glycerin or oil had the advantage of not producing these unpleasant constitutional effects and of not being painful when injected, but, on account of its viscosity, it was necessary to employ needles of large caliber. It was well to remember that all iodoform solutions were prone to undergo chemical decomposition, especially when nearly saturated or when exposed to sunlight. Camphor had the property of increasing the solubility of iodoform in these fluids, so that a saturated solution of camphor in olive oil would dissolve six per cent. of iodoform. No definite rule could be laid down as to the amount of iodoform which could be injected without danger of producing constitutional effects; thus, a grain and a half had been known to give rise to these symptoms, while in other cases no such result had followed the introduction of one hundred and fifty grains. It was generally considered that thirty grains of iodoform might be injected, but the difference of action of the ethereal and the glycerin solution must be borne in mind.

The author then spoke of the different manifestations of iodoform poisoning, those cases being considered the most dangerous in which there was a rapid and compressible pulse, either with or without fever. Then the presence of iodoform in the human system was shown by a disagreeable taste; the introduction of a silver piece into the mouth would immediately develop a garlic taste, which, according to Poncet, was characteristic of the presence of iodoform. Another test was the production of a canary-yellow color when calomel was mixed with the saliva. He related in detail the histories of two cases to illustrate the action of the iodoform in the treatment of joint disease. In the first one the patient, aged eighteen, had been admitted to Bellevue Hospital on February 17, 1891, with a history of having suffered from disease of the knee joint for three years, during which time he had been treated in various ways without benefit. The synovial cavity had been greatly distended with fluid, there had been no special tenderness, and no increase in the temperature of the joint. There had been much relaxation of the ligaments, and lateral motion on hyperextension

Walking had not caused pain, but there had been so much relaxation of the lateral ligaments that locomotion had been impracticable without confining the joint with a bandage or splint. On February 21st the joint had been opened by a free incision, and its cavity thoroughly irrigated with a 1-to-2,000 solution of bichloride of mercury. Numerous melon-seed bodies had been evacuated and the wound then closed. The wound had healed by primary union and the joint had been diminished in size, but the previously overdistended soft parts had remained fleshy and the relaxed ligaments had made the joint very insecure. On April 1st the joint had been opened in two places—at the site of the former incision, and at the outer side of the quadriceps tendon—so as to lead directly into the outer pouch of the upward prolongation of the synovial cavity. After a thorough irrigation with a 1-to-2,000 solution of bichloride of mercury and the complete removal of numerous "rice-seed" bodies, the cavity had been irrigated with a ten-per-cent. ethereal solution of iodoform and the wounds closed as before. Primary union had occurred without reaction. A portion of the synovial membrane had been removed at this operation, and had been sent to Dr. Biggs, who had reported that there was no doubt about its being involved in the tubercular infection. From this time until May 1st the knee had diminished in size and increased in stability, yet the latter had not been sufficient to render the joint secure. On May 9th a small quantity of fluid had still remained in the joint, and, as the patient had been anxious to leave the hospital, two ounces of a ten-per-cent. solution of iodoform in glycerin had been injected directly into the joint cavity. There had been no reaction, and, after four or five days' rest in bed, the patient had been allowed to go around the ward, and on June 16th he had been discharged. There had been no pain, tenderness, or effusion for two weeks prior to his leaving the hospital. Should a similar case come under his observation, the author said that he should prefer to open the joint at once in two places, clean out the cavity by irrigation and manipulation, and, after perfect union had been secured, inject into the cavity two or three ounces of a ten-per-cent. solution of iodoform in sterilized glycerin or oil.

In a second case, one of old knee-joint disease, attended with considerable flexion of the leg and subluxation of the head of the tibia, occurring in a man twenty years of age, iodoform injections had been begun after other recognized methods of treatment had failed to produce any noteworthy local improvement. The case had been under the care of Dr. J. H. Girdner. Eight drops of a twenty-per-cent. solution of iodoform in ether had been injected at each of three separate points of greatest tenderness, into the deepest tissues, and perhaps some portion into the joint itself. Great pain had been produced at the site of the injection, followed by numbness of the limb, and persistent nausea for twelve hours; and as the same symptoms had followed a second injection, it had been decided to substitute a twenty-per-cent. solution of iodoform in glycerin. This latter preparation had caused less pain in the limb and no systemic disturbance. The injections had been repeated every two or three days. At the end of thirty days the joint had been free from pain and swelling, the doughy feeling had gone, there had been voluntary motion, and considerable weight could be borne by the limb. His general condition had also kept pace with the local improvement and at the present time the limb was nearly as strong as the other; there was considerable motion, so that the patient could walk on it without artificial aid. There could be no reasonable doubt of the tuberculous nature of the disease of the joint in this case, or of the curative effects of iodoform.

Dr. A. B. JUDSON had failed to see the necessity or desirability of using iodoform in joints which were under mechanical treatment. In children thus affected, local medication might be

ignored in favor of general treatment. He believed that the trouble was not so much a local fault as a failure, for some reason or other, of the system to arrest the morbid action and repair the damage already done, and the system, rather than the affected part, should receive most attention. Mechanical treatment was a local application, but its indirect action was of the utmost importance in relieving pain, permitting sleep, facilitating locomotion, and promoting general well-being. It prevented the injurious effects of habitual trauma, and provided for ultimate symmetry and ability. Beyond this roborant and reconstructive treatment, general medication was in order, reinforced by hygiene and an abundance of rich and wholesome food, in which cream and other forms of animal fat should be in excess. He believed the effects thus produced left no room for the administration of anti-strumous injections.

Dr. ROYAL WHITMAN had been surprised to hear the previous speaker express doubt as to the influence of iodoform on tuberculous processes, for it was not a matter of opinion, but of record. Bruns, Krause, and other investigators had shown that the membrane of tuberculous abscesses ordinarily consisted of four layers: (1) An outer layer of thick porous tissue, (2) a layer of spindle cells in a state of active proliferation, (3) actual tuberculous granulations, and (4) necrotic and degenerated tissue. The two inner layers contained the tubercle bacillus. Under the iodoform treatment it was found that healthy granulations sprang from the spindle-cell layer, the bacilli disappeared, and the tuberculous granulations and inner layer were converted into a fluid, which might be absorbed or withdrawn with an aspirator. Arens, in a recently reported series of two hundred and fifty-five cases of tuberculous disease of various joints, had stated that under the iodoform treatment forty per cent. had shown very marked improvement. The most favorable cases were those of disease of the wrist and elbow. Trendelenburg had given up the use of the ethereal solution in his clinic because of the pain produced. Instead, he used a twenty-per-cent. solution of iodoform in oil, injecting about one teaspoonful at intervals of eight days. Krause used a larger quantity—thirty to eighty cubic centimetres, injecting at intervals of three weeks. Bruns stated that eighty per cent. of all abscesses might be made to disappear by the use of iodoform, and the specific action of this drug on the tubercle bacillus seemed to be very generally recognized. Trendelenburg was now using oil and iodoform at a temperature of 100° F., with the object of making a solution of the iodoform in the oil and of securing its deposition in a more finely divided state.

Dr. SAMUEL LLOYD said that he had seen very remarkable results in his clinic following the use of injections of iodoform emulsion, both in joint difficulties and in tubercular adenitis; in fact, in the latter class of cases they acted so satisfactorily that they had been used almost to the exclusion of operative measures. In many cases where tubercular deposits had been found in the lungs, the change had been very decided after the injections, especially when these had been pushed up to the point of producing constitutional effects. In one or two cases where operative procedures had been undertaken, and, secondarily, injections had been used on a recurrence of the disease, the improvement had been much more rapid than after the first operation when the iodoform had not been employed. When using the iodoform injections in abscess cavities the results had not proved good until the cavity of the abscess had been washed with hot water or with some antiseptic solution. It was advisable, then, to inject the emulsion up to the point of causing some distention. Dr. N. Senn had had a similar experience, and in his recently published article on this subject he had said that he used weaker solutions of iodoform, but in larger quantities.

Dr. R. H. SAYRE said that in using these injections he had felt the necessity of employing the iodoform in a more finely divided state, and therefore he thought it was an advantage to use the heated oil. He recalled two cases of suppurating ankle-joint disease, one of which had been treated by injections of iodoform, and the other by injections of aristol. They had done equally well, and after about two months of treatment the evidences of inflammation had entirely disappeared and there had been no pain or tenderness about the ankle. A splint had been applied to take off the weight of the body. In a case of tubercular inflammation of the thumb he had obtained a good result from the injection of a ten-per-cent. solution of iodoform, and likewise in some abscesses.

Dr. H. L. TAYLOR said that he indorsed what Dr. Judson had said as to the value of mechanical treatment, and yet welcomed the method presented in the paper. His experience with iodoform in a few cases had convinced him that it had a specific action on tubercular tissue. One of his most striking cases was that of a typically tubercular subject, a youth of seventeen years, who had been for some time under observation of Dr. Da Costa for suspected pulmonary disease. He had been hobbling about without crutches, in spite of advice, for about a year after the development of symptoms of tarsal disease before he had come under the speaker's care. He had been made to use crutches, and the foot had been immobilized with an apparatus. After some months, a sinus having appeared, on the advice of Dr. Abbe, injections of an ethereal solution of iodoform into the joint had been begun. He could honestly say that the entire appearance of the affected parts had been changed after one injection, and the subsequent progress of the case to complete cure, although slow, had been steady. He had also used the iodoform emulsion in sinuses about joints, and he believed that this treatment produced beneficial effects, independently of its antiseptic action.

The CHAIRMAN said that about two years ago, while visiting the clinics in Germany, he had seen a good deal of this treatment with the ethereal solution of iodoform, and he had been impressed with the great frequency of symptoms of iodoform poisoning and with the general disregard of mechanical treatment shown by the German surgeons. Still he believed that in these iodoform injections we had a valuable adjunct to mechanical treatment, and one which had not been sufficiently tested by American orthopaedic surgeons.

Dr. BRYANT said that he had not had the slightest idea of substituting the iodoform injections for mechanical treatment, but he had thought that it could not fail to be a valuable adjunct to this treatment, on account of its well-known influence upon the tubercle bacilli, and because the injections could be made so easily. In the case of knee-joint disease that he had described, where the rice and lemon-seed bodies were in such large numbers, he did not believe that mechanical treatment alone would have cured the case; in fact, the patient had had this treatment and had not been benefited by it.

## Book Notices.

---

*Text-book of Comparative Anatomy.* By Dr. ARNOLD LANG, Professor of Zoology in the University of Zurich, etc. With Preface to the English Translation by Professor Dr. ERNST HAECKEL, F. R. S., Director of the Zoological Institute in

Jena. Translated into English by HENRY M. BERNARD, M. A. Cantab., and MATILDA BERNARD. Part I. London and New York: Macmillan & Co., 1891. [Price, \$5.50.]

THE constantly increasing attention that is being given in our American colleges to the subject of comparative anatomy makes the appearance of this translation of Professor Lang's famous work particularly timely and appropriate.

In the commendatory preface to the volume Professor Haeckel states that the author has, more than any former writer, made use of the comparative history of development in explaining the structure of the animal body, endeavoring always to give the phylogenetic significance of ontogenetic facts.

The present volume has chapters on the *Protozoa*, *Metazoa*, *Platodes*, *Vermes*, and *Arthropoda*. Prefacing each chapter there is a systematic review of the various classes and orders of each race, and at the close there is a list of the important literature on the subject.

The volume contains almost four hundred excellent illustrations, and is provided with a good index.

*The Physician as a Business Man; or, How to obtain the Best Financial Results in the Practice of Medicine.* By J. J. TAYLOR, M. D. Philadelphia: The Medical World, 1891. Pp. 144.

THE physician is proverbially a poor business man. There is probably no class of men who realize so little financially from their labors and from the capital invested, and who lose so large a percentage of their just dues. The very nature of the general practitioner's duties renders a certain amount of loss a necessity which the humane man can never prevent. Much, however, is preventable by good business methods. Such methods the writer of this little book endeavors to explain, and with a fair degree of success. The general principles proposed are excellent, but details regarding fees and methods of collection can apply only to limited regions, as customs in these matters are so widely different.

The best part of the book is that devoted to a discussion of the true value of medical and surgical services. The doctor's losses are largely due to lack of appreciation of such value by himself as well as by the patient, by long terms of credit, and by carelessness and loose business methods.

*History of Circumcision from the Earliest Times to the Present. Moral and Physical Reasons for its Performance, with a History of Eunuchism, Hermaphroditism, etc., and of the Different Operations practiced upon the Prepuce.* By P. C. REMONDINO, M. D. (Jefferson), Member of the American Medical Association, of the American Public Health Association, and of the State Board of Health of California. Philadelphia and London: F. A. Davis, 1891. Pp. x-346.

THIS book, while it evinces great study and research and contains a vast store of information regarding the subjects of which it treats, contains also a large amount of rubbish, some of it extremely disgusting. It is a strange combination of science and balderdash. The astonishing statement is made that a large number of physicians have had themselves circumcised while in college or after entering practice, as the result of their own convictions regarding its value. The author's sympathy for "the unlucky and unhappy wearer of a prepuce" will seem to most readers to be wasted. The more serious and scientific parts are marred by his strong prejudice in favor of the operation, which has biased his judgment and rendered his conclusions of little value. From a literary point of view the work is slovenly in the extreme. As a history of circumcision, emascu-

lation, castration, eunuchism, infibulation, muzzling, and numerous other strange practices, it contains much that is curious and interesting, and will repay reading.

#### BOOKS, ETC., RECEIVED.

A Treatise on the Ligation of the Great Arteries in Continuity. With Observations on the Nature, Progress, and Treatment of Aneurysm. By Charles A. Ballance, M. B., M. S. Lond., F. R. C. S., Assistant Surgeon to St. Thomas's Hospital, etc., and Walter Edmunds, M. A., M. C. Cantab., Resident Medical Officer, St. Thomas's Home. Illustrated by Ten Plates and Two Hundred and Thirty-two Figures. London and New York: Macmillan & Co., 1891. Pp. xxviii to 568. [Price, \$10.]

The Chinese, their Present and Future: Medical, Political, and Social. By Robert Coltman, Jr., M. D., Surgeon in Charge of the Presbyterian Hospital and Dispensary at Teng Chow Fu, etc. Illustrated with Fifteen Fine Photo-engravings. Philadelphia and London: F. A. Davis, 1891. Pp. viii to 212. [Price, \$1.75.]

The Treatment of Typhoid Fever, and Reports of Fifty-five Consecutive Cases, with only One Death. By James Barr, M. D., Physician to the Northern Hospital, Liverpool, etc. Introduction by W. T. Gairdner, M. D., LL. D., Professor of Medicine in the University of Glasgow, etc. London: H. K. Lewis, 1892. Pp. x to 212.

Hospitals and Asylums of the World; their Origin, History, Construction, Administration, Management, and Legislation, etc. By Henry C. Burdett, formerly Secretary and General Superintendent of the Queen's Hospital, Birmingham, etc. London: J. & A. Churchill, 1891. Vols. i and ii. Pp. xvi—701; x—348.

Nursing in Abdominal Surgery and Diseases of Women. A Series of Lectures delivered to the Pupils of the Training School for Nurses connected with the Woman's Hospital of Philadelphia, comprising their Regular Course of Instruction on such Topics. By Anna M. Fullerton, M. D., Physician in Charge of and Obstetrician and Gynecologist to the Woman's Hospital of Philadelphia. Illustrated. Philadelphia: P. Blakiston, Son, & Co., 1891. Pp. xiii—17 to 284.

Syphilis in Ancient and Prehistoric Times. By Dr. F. Buret, Paris, France. Translated from the French, with Notes, by A. H. Ohmann-Dumesnil, M. D., Professor of Dermatology and Syphilology in the St. Louis College of Physicians and Surgeons. "Syphilis To-day among the Ancients." In Three Volumes. Volume I. Philadelphia and London: F. A. Davis, 1891. [Price, \$1.25.] [No. 12 in the *Physicians' and Students' Ready-reference Series.*]

Diseases of the Skin. A Manual for Practitioners and Students. By W. Allan Jamieson, M. D., F. R. C. P. Edin., Extra Physician for Diseases of the Skin, Edinburgh Royal Infirmary, etc. Third Edition, revised and enlarged. With Woodcut and Nine Colored Illustrations. Philadelphia: Lea Brothers & Co., 1892. Pp. xvi to 644. [Price, \$6.]

Consumption: How to Prevent it and how to Live with it. Its Nature, its Causes, its Prevention, and the Mode of Life, Climate, Exercise, Food, Clothing necessary for its Cure. By N. S. Davis, Jr., A. M., M. D., Professor of Principles and Practice of Medicine, Chicago Medical College, etc. Philadelphia and London: F. A. Davis, 1891. Pp. viii to 143. [Price, 75 cents.]

Tubal and Peritoneal Tuberculosis, with Special Reference to Diagnosis. By George M. Edebohls, M. D., New York. [Reprinted from the *Transactions of the American Gynecological Society.*]

Addresses on Anatomy. I. Comparative Anatomy as a Part of the Medical Curriculum. II. On the Teaching of Anatomy to Advanced Medical Students. By Harrison Allen, M. D., Philadelphia.

The Treatment of Appendicitis, with Illustrated Cases. By J. E. Summers, Jr., M. D., Omaha. [Reprinted from the *Omaha Clinic.*]

The Relation of Orthopædic Surgery to General Surgery. By Newton M. Shaffer, M. D., New York. [Reprinted from the *Boston Medical and Surgical Journal.*]

Tumor of the Brain. A Clinical Lecture delivered at the Arapahoe County Hospital, October 31, 1891. By J. T. Eskridge, M. D., Denver. [Reprinted from the *Denver Medical Times.*]

Bromoform in the Treatment of Pertussis. By E. J. Mellish, M. D. [Reprinted from the *Chicago Medical Recorder.*]

A Case of Orbital Cellulitis and Primary Mastoiditis Interna complicating Influenza; Opening of Mastoid Process; Recovery. By Charles Zimmermann, M. D., Milwaukee. [Reprinted from the *Archives of Otolaryngology.*]

The Treatment of Inguinal Hernia. By Alexander Dallas, M. D., New York. [Reprinted from the *Medical News.*]

Biennial Report of the Board of Trustees and Superintendent of the East Mississippi Insane Asylum, for the Years 1890 and 1891.

Report of the Sixth Annual Meeting of the Association of Executive Health Officers of Ontario, held at Trenton, August 18, 19, and 20, 1891.

Roosevelt Hospital, New York. Twentieth Annual Report, from January 1, 1891, to December 31, 1891.

## Reports on the Progress of Medicine.

### REPORT ON OPHTHALMOLOGY.

By CHARLES STEDMAN BULL, M. D.

**Some Experiments to determine the Lesion in Quinine Blindness.**—De Schweinitz (*Ophth. Rev.*, February, 1891) gives the details of eight experiments on dogs, and draws the following conclusions: When quinine is given hypodermically to dogs in quantities varying from one grain to the pound to four grains to the pound, blindness, generally accompanied by other general disturbance, is apparent in from three to fourteen hours. The exact date of the onset of the loss of vision was not determined; the earliest date of its appearance after injection which was noted was three hours. The blindness remained practically complete in one animal twenty-nine days after a single injection of three grains and three quarters to the pound. In one there was slight return of vision after thirty-six hours of blindness. In these animals the ophthalmoscopic picture was similar to that seen among human beings with quinine amaurosis; in one there was complete obliteration of the vessels on the optic disc, and in another blurring of the edges of the optic discs. In all, the pupils were immovably dilated. There were no very gross lesions, with one exception, in either the cross-sections of the nerves, or in the optic-nerve entrances, or the retina. In one case there was decided dilatation of the blood-vessels, and the central vein was plugged with a clot, with long fibrin prolongations, while white thrombi filled the smaller veins. In the other cases there was some dilatation of the blood-vessels at the nerve entrance, but to a much smaller degree. The transverse cuts of the nerves did not exhibit any marked lesion. In a few there appeared to be some slight increase in the connective tissue. In others the nerve bundles between the trabeculae of connective tissue were wider than normal. As regards the brain, the same lesion was present in all instances in sections taken from the cuneus—namely, a remarkable dilatation of the pericellular lymph spaces, with degeneration of the protoplasm of the cell. In dogs blind for a month there was no atrophy of the nerve fibers in the sense in which the word is ordinarily used; nor was there any appearance in the earliest stage of the blindness of neuritis.

**Operations upon Eyes blinded by Sympathetic Ophthalmitis.**—Story (*Ophth. Rev.*, March, 1891) lays down the following propositions for discussion: 1. No operation should be performed on an eye until all signs of sympathetic inflammation have disappeared, unless the intra-ocular pressure is acutely glaucomatous. 2. If an operation must be performed for glaucoma during active "sympathy," it should be a corneal or scleral incision, and no iridectomy should be attempted. 3. When all inflammation has disappeared, the best method of operating is that of Mr. Critchett, by which the iris is not wounded, hemorrhage is reduced to a minimum, and the least possible occasion is given to inflammatory reaction; and, lastly, no large opening is made in the globe through which a fluid vitreous may escape, as it does occasionally through an iridectomy, in quantities sufficient to produce collapse of the eyeball.

**Aniridia and Glaucoma.**—Collins (*Ophth. Rev.*, April, 1891) reports three cases bearing on this subject. The *first* was in a man, aged thirty-four, who had good sight when a boy, but could not bear a bright light. For two years previous to his admission to the hospital there had been a gradual failure of sight in his left eye, while that of the right, previously defective, had improved. He had worn glasses of sph. + D. 6 for eighteen months. He had three children, two of whom had the same ocular malformation as himself. An examination showed complete absence of both irides. Some fine granular opacities and a few vacuoles were seen in the right lens. There was deep cupping of the optic nerve in this eye. The tension was increased and vision was  $\frac{3}{60}$ . The nasal and lower parts of the field were much contracted. The left lens was opaque, and tension of the left eye was increased. The *second* case was in a woman, aged twenty-two, with congenital aniridia in both eyes and a perforating ulcer of the right cornea. There was ptosis with marked nystagmus. The left eye was normal as to cornea and lens. The right eye was enucleated, and, on its being opened, the ciliary processes were found stretched and atrophied, especially in the region of the ciliary staphyloma. The optic disc was deeply cupped, and the retina and chorioid were detached. The filtration area of the cornea was blocked by the intimate bit of the rounded nodule in which the ciliary body terminated. The examination showed that the apparent complete congenital aniridia, or the presence of a congenital coloboma of the iris, did not diminish the likelihood of a relief of tension being obtained by a sclerotomy in the former case, or an iridectomy in the latter. The *third* case was in a man, aged twenty-six, who twelve years before had had the right eye wounded by a chisel, which had caused blindness. The blind and staphylomatous eye was excised. The examination showed a thinning and bulging of the sclerotic in the whole circumference of the globe; there was a dense white cicatrix passing across the entire cornea, and adherent to this was the lens capsule. The nucleus and most of the cortex of the lens were absent. There was complete aniridia; the ciliary body was stretched and atrophied, and the optic disc was deeply cupped. The ciliary processes were intimately adherent to the posterior surface of the cornea at its periphery, in the region of the ligamentum pectinatum.

**Results of operating in Cases of Xerosis coexisting with Trichiasis.**—Scott (*Ophth. Rev.*, June, 1891) reports two cases illustrating this subject. The *first* was in a man, aged forty-five, who had trichiasis and xerosis in both eyes. He was seen three months after the operation for trichiasis, and in both eyes the cornea, fully sensitive, was clear and its surface was polished. The lacrymal secretion was normal, and the ocular conjunctiva had quite lost its former dried appearance and was smooth, glistening, and sensitive. The *second* case was also in a man with exactly the same condition, but in one eye.

**Filamentous or Fibrous Formation in the Cornea.**—Czermak (*Kl. Mon. f. Aug.*, July, 1891) draws the following conclusions from his observations: 1. Exudative material coming from an inflamed conjunctiva may, in some way not yet perfectly understood, gain entrance into the cornea through some ulcerated spots. 2. These filamentous structures contain mainly leucocytes within their vitreous basic substance. 3. By the movements of the eyelid and eyeball they undergo a milling or rubbing, which causes deformity in the shape of the cells, and, by a pressing and rotation together, leads to the development of these spiral filamentous formations.

**Parageusia with Ophthalmoplegia.**—Wherry (*Ophth. Rev.*, June, 1891) describes the case of a man, aged forty-seven, who had homonymous diplopia, which increased on looking toward the right side. There were no signs of tabes or of active neuritis. Both irides were dilated and immovable. Vision was not affected. The attack began three days previously while at dinner. He noticed that everything tasted bitter, and there was occasional diplopia. Two weeks later there was marked divergence with crossed diplopia, though each eye could move separately in every direction. Convergence was impossible. Some spots of numbness were noticed on the outer side of the left thigh and left little finger. There was severe nocturnal pain in the head. The parageusia lasted acutely during five days. The external squint and dilatation of the pupils lasted ten days longer, and then disappeared gradually. It was thought probable that the ocular symptoms were due to a syphilitic

lesion affecting the nuclei of the third nerve about the aqueduct of Sylvius, probably very minute.

**The Treatment of Squint by Advancement of the Recti Muscles.**—Bronner (*Ophth. Rev.*, July, 1891) bases his opinions on the records of fifty cases of strabismus treated by advancement of one of the recti muscles according to Schweigger's method. He thinks it of the greatest importance that the size and condition of the muscle should be ascertained as nearly as possible before the advancement is performed. In many of the cases tenotomy of the antagonistic muscle was necessary, and in some tenotomy or advancement had to be done on the muscles of the fellow-eye. In cases of divergent strabismus, tenotomy of the externus and advancement of the internus were necessary. In no case should the same muscle be cut more than once. Bronner thinks that advancement of the muscle is the best operation in all cases in which the squinting is amblyopic, and in which the angle of deviation measures more than 30°.

**Incipient Cataract; its Ætiology, Treatment, and Prognosis.**—Risley (*Ophth. Rev.*, August, 1891) refers to former papers of his in which the opinion was urged that, by regarding the hard cataract as one of the unavoidable concomitants of old age, the tendency had been to overlook the more potent factors in its production to be found in the pathological states of the intra-ocular tunics. He thinks the opaque lens must be regarded as an extraordinary condition to be explained by other causes than senility. In many cases it is well known that the apparently progressing opacity of the lens can be arrested; in others, the rapidity of its increase can be greatly retarded, thus maintaining a useful acuity of vision for a longer time, and, failing in this, the treatment instituted will place the eye in a more favorable state for operative interference. There are many cases of eyes suffering from irritative and chronic inflammatory processes of the retina and chorioid, which, as a rule, do not present the gross ophthalmoscopic changes which characterize the more destructive forms of retinal and chorioidal disease. These eyes are weak eyes, suffering from "eye-strain," and the majority of them show some refractive error, usually astigmatism, as well as muscular anomalies. The uncorrected errors of refraction are doubtless the most frequent cause of the conditions here described. In these cases there are almost always some changes in the lens, usually peripheral, which might come under the head of "incipient cataract." The results of treatment in this group of cases, faithfully pursued, are sufficiently encouraging. The improvement of vision noted in almost all the cases successfully treated was *in no case due to the absorption of the opacities already formed in the lens*, but to the improved condition of the chorioid and retina and the clearing up of the vitreous webs, or the granular or sand-like deposit so frequently discovered in the anterior part of the vitreous body. The treatment adopted was to require as complete rest as possible from all work at a near point, the use of smoked glasses when exposed to bright light, and the local employment of mild washes and astringents to the conjunctival sac, together with the moderate use of mydriatics, preferably homatropine. Internally potassium iodide or ferrous iodide, and potassium bromide or lithia if headache was a marked symptom. Any existing error of refraction is to be carefully corrected, and the correcting glasses are to be worn constantly, suitable correction for a near point being allowed for all necessary work. Risley draws the following conclusions: 1. Cataract, though a disease of advanced life, is not necessarily a senile change, but originates in local pathological states involving the nutrition of the eye itself. 2. In the stage of incipient cataract is amenable to treatment by such measures as are calculated to remove the pathological conditions upon which it depends, and we are justified in giving a more hopeful prognosis to many persons with commencing cataract. 3. Although the treatment may fail to arrest the progressive degeneration of the lens, the eye will still be in a better condition to undergo the trials of surgical interference.

**The Consensual Pupillary Light Reflex in Cases showing the Argyll Robertson Pupil Symptom in One Eye.**—Jessop (*Ophth. Rev.*, August, 1891) gives notes of five such cases; three were cases of tabes, one of doubtful tabes, and one probably of sclerosis of the posterior and lateral columns. In all, though the contraction of the pupil associated with accommodation was present in both eyes, the direct and consensual light reflex was lost in one and the same eye. In all

the cases the consensual light reflex was present in the sound eye, thus showing that the optic nerve was capable of carrying impulses to the light-reflex center of the opposite eye. The lesion in these cases is probably one affecting the light-reflex center for one eye near the terminations of the afferent part of the reflex arc. These cases strengthen and uphold the theory of the decussation of the optico-pupillary fibers.

**The Action and Uses of Prismatic Combinations.**—Percival (*Ophth. Rev.*, October, 1891) believes that prisms which correct the muscular defect completely will be almost always successful in these cases of hyperphoria, as the error in each eye rarely exceeds  $2^\circ$ , and is generally much less. The tendency to deviation in the horizontal plane requires closer study. There are two classes of cases of this nature which must be carefully distinguished: First, those characterized by feebleness of one or more of the muscles, with which is associated an impairment of movement. Second, those in which the range, though not contracted in extent, is in an unavailable situation. In such cases, indeed, the amplitude of the movement is often greater than normal, yet symptoms arise owing to the fact that the position of minimum tension is not consistent with parallelism of the visual axes. In the first class of cases, due to muscular weakness, prisms to relieve the defect should never be given if cure of the affection is the object in view. Progressive deterioration of the condition, necessitating repeated alterations in the glasses, is almost invariably the result if this line of action is pursued. It sometimes happens that our object is not to cure the affection—that is, in those paralytic cases which we regard as incurable. It is in the second class of cases—in those in which the range of movement is represented by an angle of  $18^\circ$  or more—that prismatic combinations may be ordered to be constantly worn, and here they are only applicable when the error is not greater than  $2^\circ$  in each eye. If the defect exceeds this limit, tenotomy of the preponderating muscles is indicated. Tenotomy has the disadvantage of diminishing the amplitude of movement, so that, unless the range is of the normal extent, advancement of the feeble muscles would be preferable, as thus the range is increased in amplitude, while it is also rendered more available by the alteration of its position.

**The Correction of Aphakia by Glasses.**—Dimmer (*Kl. Mon. f. Aug.*, April, 1891) thinks that when a spherocylindrical lens is ordered for an aphakial eye, after the usual method of examination, the glass as ground by the optician overcorrects the error. This is particularly the case in spherical lenses of more than D. 10, in combination with a cylindrical lens, and the visual acuity may thus be apparently decidedly diminished. In order to avoid this it is necessary to determine the error of refraction by a plano-convex spherical glass placed in front of the cylindrical glass in the test-frame.

**The Ophthalmoscopic Appearances in Hypermetropia and their Significance.**—Bristowe (*Ophth. Rev.*, November, 1891) considers that the peculiar appearance called the "hypermetropic disc" is found at all ages, and probably continues through life. It in no way interferes with the acuteness of vision, nor damages the usefulness of an eye, nor has it any definite relation to the degree of hypermetropia. An intense "pseudo-neuritis" may be present with a very low degree of error. The "watered-silk" retina exists only in early life, probably to infancy, and disappears with the advent of puberty. The "concentric striation" appears under exactly the same conditions as does the "watered-silk" retina, and like it has no relation either to the acuteness of vision or to the degree of error. He thinks there are two forms of hypermetropia—one where the eyeball is fully formed but has an abnormally small antero-posterior diameter, and another in which the hypermetropia is due to the immature development of the globe and its contents.

**Papilloma of the Cornea.**—Ayres (*Ophth. Rev.*, September, 1891) reports a case of this nature occurring in a woman, aged fifty, who had a large growth on the anterior portion of the left eye, involving the entire front of the ball. It looked like a cauliflower and projected one centimetre from the sclera; its horizontal diameter was 3.5 centimetres and its vertical diameter two centimetres. It began to grow six years before. Four years later it was excised, but grew again very rapidly. A portion was then excised every few weeks for six months. In August, 1887, it was as large as a hazel-nut and protruded between the lids. In August and September, 1887, small portions

were again cut away. In May, 1889, it had grown to an immense size, and was removed by Ayres, together with the eyeball. On examination, its structure was found to consist of exceedingly delicate papillæ, which appeared to spring from almost the entire anterior surface of the cornea. The growth probably originated in the conjunctiva.

**The Pathology of the Ophthalmoplegiæ.**—Collins and Wilde (*Ophth. Rev.*, October, 1891) point out in this paper that accumulating evidence makes it impossible any longer to regard a group of symmetrical oculo-motor paralyses as isolable into a unique malady called ophthalmoplegia, but that these must be considered in relation to ocular moroplegia on the one hand, and bulbar paralysis, locomotor ataxy, and infantile spinal paralysis on the other. The so-called ophthalmoplegia interna can no longer be classed as a peripheral palsy or as due to disease of the lenticular ganglion. Anatomical, physiological, and clinical facts point to nuclear lesion, most probably in the anterior part of the floor of the aqueduct of Sylvius. The authors have collected 141 cases of ophthalmoplegia. Syphilis was the cause in at least thirty-three per cent. When palsy of either iris or ciliary muscle coexisted with extra-ocular palsy, it was more frequently the former, which fact was a corollary to the accepted relation of the centers for them in the nucleus of the third nerve.

**A Theory of Glaucoma.**—Rheindorf (*Kl. Mon. f. Aug.*, February, 1891) does not believe that the existence of increased tension alone, or the so-called typical pressure excavation alone, or both these symptoms together, suffice to justify a diagnosis of glaucoma. There must be also present the clinical symptoms in the pupil, iris, and anterior chamber. He advises the removal of the transparent or cloudy lens in glaucoma, and rupture of the hyaloid membrane under the following circumstances: 1. When the anterior chamber does not re-establish itself after iridectomy. 2. When the anterior chamber does re-establish itself, but the visual acuity continues to diminish. 3. In absolute glaucoma in place of enucleation.

**The Formation of Vesicles at the Equator of the Lens.**—Magnus (*Kl. Mon. f. Aug.*, September, 1891) describes a peculiar pathological condition met with in some eyes. It consists of large vesicles along the equator of the lens and involving the neighboring parts of the lens. They are cone-shaped, perfectly transparent, and of varying size. Their broad bases rest against the surface of the lens and their points extend partly into the posterior chamber and partly into the canal of Petit. The cone-shape is always marked, but the slope from base to apex is gradual. The surface is smooth and without a wrinkle. The lens in their vicinity is perfectly transparent. The shape of the cones varies with the direction of the illumination. Sometimes these cones form a continuous circle round the lens. Magnus thinks that they have some connection with the fibers of the zonule. They vary in number as well as in size. They are probably produced by an exudation of fluid beneath the capsule, which lift the latter like a vesicle from the stratum beneath.

**The So-called Blennorrhœa of the Lacrymal Sac in New-born Infants.**—Peters (*Kl. Mon. f. Aug.*, November, 1891) thinks there are a number of such cases in very young infants which are not caused by inflammation of the mucous membrane, and hence should not be called "blennorrhœa." They are due to a defective absorption of the tissue at the entrance of the lacrymal duct, which hinders the exit of the cellular material in the lumen of the duct. There is therefore an actual atresia of the lacrymal duct. Here it suffices to press out the contents of the sac and then to fully irrigate the eyes, in order to bring about a perfect cure.

**A Case of Malignant Fibroid of the Orbit.**—Dunn (*Amer. Jour. of Ophth.*, December, 1890) describes an interesting case of orbital tumor occurring in a negro, aged nineteen, who had a growth protruding from between the lids of his left eye. It had made its appearance about nine months previously. Four months before the growth had been partially removed. Since then it had grown very rapidly, and when Dunn saw him it had filled the interpalpebral space. It consisted of two parts, an encapsulated central part and its prolongations along the conjunctiva and subconjunctival tissue of the lower *cul-de-sac*. The encapsulated portion was as large as a hickory-nut and pushed the eye upward and backward. The eyeball was apparently perfectly healthy,

but below were a number of small vessels running from the tumor to the edge of the cornea. The surface of the growth was red, rough, and warty, and was covered with a dirty, purulent secretion. It was sensitive to the least pressure. The eyeball was first enucleated, and the growth was then removed in what seemed its entirety. It was nowhere adherent to the eyeball. On section, it was found to consist mainly of bands of fibrous tissue and individual fibrille, and contained but few small round cells.

**The Treatment of Blepharospasm.**—Allport (*Amer. Jour. of Ophth.*, January, 1891) advises that spasm of the orbicularis muscle be treated systematically by stretching its fibers forcibly. The procedure consists merely in placing a strong, short speculum between the lids, and opening its blades until it is deemed that the muscle has been thoroughly stretched. The speculum is then firmly set and allowed to remain in its expanded condition for about five minutes, when it should be removed. The procedure is quite painful, and in some cases may require general anesthesia. It is often advisable to repeat the operation several times at intervals of a few days.

**The Injurious Influence of the Accommodation upon the Increase of Myopia of the Highest Degrees.**—Fukala (*Amer. Jour. of Ophth.*, March, 1891) considers that the loss of the power of accommodation in myopes of the highest degree is not a disadvantage, but is of considerable advantage. The use of the accommodation, according to eminent authors of our own times, injures such eyes, in that the myopia is increased, because accommodation increases the intra-ocular pressure. Myopes use their accommodation less than hypermetropes, therefore the accessory portion (or circular fibers) atrophies. The atrophy once begun, and being transmitted by heredity, is certain to progress, as does also the elongation of the optical axis. Under the influence of this condition the ciliary muscle is more and more changed into a tensor chorioideæ, which in its turn causes the pathological changes in the sclerotic and chorioid. By its contraction the ciliary muscle of the myope must necessarily pull more forcibly on the chorioid than the muscles of the hypermetrope, in whose eyes the circular fibers are much more developed.

**Remarks on the Ophthalmometer of Javal and Schiotz.**—Ostwald (*Rev. gén. d'ophthal.*, March 31, 1891) draws the following conclusions from his use of this instrument: 1. This ophthalmometer indicates exactly the radius of the cornea. 2. The number of dioptries indicated by the instrument is a quarter too great. 3. The steps of the sight are also a quarter too great. 4. The astigmatism of the cornea is therefore only about three quarters of what the instrument shows. 5. A good part of what has been regarded as correcting contractions of the ciliary muscle is explained by this difference between the values indicated by the ophthalmometer and the actual values of the corneal astigmatism. 6. Hence the results and conclusions from the observations made with this ophthalmometer must be carefully controlled by other means of examination. 7. The ophthalmometer of Leroy and Dubois has much greater precision, though even here the values given are a quarter too great.

**The Refracting Power of the Cornea; Ophthalmometry and the Correcting Cylinder for the Corneal Astigmatism.**—Ostwald (*Rev. gén. d'ophthal.*, May-June, 1891) gives the following *résumé* of his observations: 1. The refracting power of different meridians of the cornea is found a quarter too large by the ophthalmometers actually in use. The same is true of the corneal astigmatism. 2. The corneal astigmatism is not identical with the correcting glass placed in front of the cornea, but is a quarter less. The correcting cylinder should not be considered as a separate and distinct glass. It only represents the difference between the two spherical glasses which correct the ametropia of the two principal meridians.

**The Micro-organism of Trachoma, Microsporion Trachomatosum.**—Noiszewski (*Ctrbl. f. prakt. Aug.*, March, 1891) has discovered a micro-organism which differs from any hitherto described. By the aid of a certain solution of gold and glycerin and by the simultaneous action of the sun's rays on the degenerated tissue of the conjunctiva, he has found the micro-organisms of trachoma, which consist of mycelium, hyphens, and conidia in irregular masses. He has succeeded in producing cultures on gelatin and causing them to grow in calves' eyes, and in these cultures the long, perfectly straight lines of *Micro-*

*sporion trachomatosum* are very characteristic. Inoculations of pure cultures upon the conjunctiva of rabbits always give positive results, but only after four or five weeks have elapsed.

**The Action of Tuberculin on the Inoculated Tuberculosis of the Rabbit's Eye.**—Alexander (*Ctrbl. f. prakt. Aug.*, July, 1891) gives the following results of his experiments: 1. The tuberculous process in the eye was not arrested by the injections, but steadily advanced. 2. The necrosis of the tuberculous tissue showed no difference in any of the animals under observation. 3. Hemorrhages appeared in all three of the injected cases, but did not occur in the fourth animal, used for a check experiment. 4. The number of tubercle bacilli were much greater in the three injected animals than in the fourth "control animal." 5. The shape and appearance of the bacilli were in all cases perfectly normal.

**A Case of Lepra of the Eye.**—Hirschberg (*Ctrbl. f. prakt. Aug.*, October, 1891) reports a case of nodular lepra of the eye occurring in a Greek, aged thirty-nine, who had lived for ten years in upper Egypt, and who had suffered from general lepra for about six years and from ocular lepra for a year. The right eye read Sn. XII at six inches, the left eye read Sn. 1½ at the same distance. On the temporal margin of the cornea in the right eye there was a reddish nodule on the sclera, about 8 mm. long in a horizontal diameter, 6 mm. wide, and 4 mm. thick. The nodule encroached on the cornea. There was a grayish exudation upon the iris in the inferior quadrant reaching to the periphery. There were also posterior synechie. The left eye showed a similar but smaller nodule exactly at a corresponding spot, which was partially separated from the cornea, but sent a tongue of infiltration into the cornea. The patient declined any operative interference.

**The Gland of the Aqueous Humor, Ciliary Processes, or Uveal Tract.**

—Nicati (*Arch. d'ophthal.*, xi, 1 and 2) draws the following general conclusions from his investigations: The aqueous humor is secreted by the surface which covers internally the ciliary processes, from the ora serrata to the commencement of the iris. Conducted by the canal of Petit, the openings of the spaces between the ciliary processes and the suspensory ligament, the posterior chamber and the pupil, it is emptied into the anterior chamber, whence it is absorbed by the lymphatic channels of the iris. This secretion is the product of a gland, the uveal gland, composed of an epithelium (pars ciliaris retinæ), a vascular and serous well or spring (the chorio-capillaris), and a contractile apparatus (the cilio-chorioid muscle), which accumulates the blood in the well. There are two kinds of aqueous humor: the ordinary, non-fibrinous variety, and the fibrinous or neuro-paralytic variety. The ordinary, non-fibrinous variety is secreted by the glandular epithelium, which interposes as a barrier to the salts introduced by the blood. It does not diffuse these salts unless the blood contains an inordinate quantity of them. Division of the cervical sympathetic favors this diffusion. The liquid of the anterior chamber is subject to an incessant movement of circulation, which prevents stasis and the deposit of opacities on the posterior surface of the cornea. The fibrinous variety, which is produced when the anterior chamber has been emptied, or the nerves of the cornea have been divided, is secreted by the interstices between the epithelial cells. Physiologically it is a reflex secretion provoked by a disturbance of equilibrium between the ocular pressure and the blood pressure. The nerves of the deep corneal layers are the peripheral seat of this reflex. The nervous mechanism of the fibrinous secretion consists of a secretory apparatus constantly in a state of tension, situated in the ophthalmic ganglion, and of an inhibitory apparatus situated in the medulla and ganglion of Gasser. The reflex or secretion occurs whenever the inhibition is suspended, either automatically by puncture, or directly by experimental division of the trifacial. Irritation of the iris and isolated paralysis of the blood-vessels of the eye hasten and exaggerate the reflex. Two pathological conditions are the result of diseased conditions of this uveal gland—glaucoma and detachment of the retina. Glaucoma is, generally speaking, synonymous with retention of the aqueous humor. This retention in youth produces distention of the channels and spaces in which the aqueous humor circulates, or anterior hydrophthalmia. It provokes, by compression of the retina, venous stasis in this membrane and in the vitreous—that is, œdema of the retina and vitreous, or hydrophthalmia posterior. The acute attack is induced by spasmodic œdema of the chorio-capillaris consecutive to irrita-

tion of the iris. The progressive anterior detachment of the retina is produced by the aqueous humor flowing through a rupture of the canal of Petit.

**Destruction of the Lacrymal Sac by the Thermo-cautery and its Total Extirpation in Fistulæ and Rebellious Tumors.**—Terson (*Arch. d'ophthal.*, xi, 3) draws the following conclusions: 1. In lacrymal fistulæ, cauterization of the sac by the thermo-cautery should be done as soon as the ordinary means of treatment have failed. 2. In certain cases of purulent inflammation, with slight dilatation and without fistula, the thermo-cautery should be employed. 3. In voluminous lacrymal tumors, and especially when the pocket is encysted, the total extirpation of the sac, followed or not by the thermo-cautery, gives the most satisfactory results.

(To be continued.)

## Miscellany.

**The Systematic Use of the Eye in Teaching Anatomy.**—The *Medical News* for February 13th publishes the following abstract of a paper read by Dr. W. P. Carr, of Washington, at the recent meeting of the Association of American Anatomists:

In this iconoclastic age a sentiment seems to be growing among medical men that lectures are of little use for didactic purposes. I wish to enter my protest against this idea, and to point out what I consider an important method of enhancing their value. The aim of the lecturer, I take it, is not so much to teach anatomic details that are much better learned from books and dissections, as to teach the student, first, how to study, how to understand, how to fix in mind the broad outlines and principles of the laws of morphology, the meaning of structures; and, secondly, to teach him those methods of observation that will enable him to add the necessary details for himself. In doing this we all recognize the importance of engaging the eye as well as the ear of the student. I have become more and more convinced of the importance of a systematic appeal to the student's eye and ear at the same time, and more and more convinced that word-pictures alone, no matter how forcible and true, make but comparatively dim and transient impressions upon the brain. Most anatomic facts are remembered by means of mental pictures—mental photographs upon the brain. Suppose you wish to remember the shape of some object. You call up a mental picture of it that you have, at some former time, stored away in your brain. Not only so, most of these mental photographs are composite photographs, made by numerous impressions, placed one over the other. Especially is this the case when the object to be remembered is a familiar one; and frequently, blended in the general outlines of the picture, and yet distinct, you may recognize some individual object of the class you wish to recall. Let me mention the great trochanter of the femur. Immediately there rises before your mind's eye a representation of the upper end of that bone. You see the trochanter, its position, shape, and relations; and most likely you recognize in the composite the outlines of some particular femur that you have handled oftenest, or that diagram in your anatomy that so frequently meets your eye. These facts show, I think, that it is by means of composite mental photographs that we retain the memory of form, memory of relation, and memory of position. The important question is how best to produce and fix these images.

Naturally, different persons possess in very different degrees this power of mental photography, as is evidenced by the ease with which some recall the features of absent friends, and the utter lack of such ability in others. But I am sure the faculty can be cultivated and brought to a satisfactory degree of efficiency in all, or nearly all, persons. To do this we must begin with simple figures, and gradually add details. Every one can remember such simple figures as the cross, square, circle, etc., but few can carry in mind a complicated arabesque. I think the older anatomists had some such idea in mind when they tried to find in the bones fanciful resemblances to familiar objects.

They were trying, perhaps unconsciously, to use some simple image already formed upon the brain as a durable basis upon which to build a more elaborate composite. But the idea may to great advantage be carried much further. I shall never forget how, when beginning the study of anatomy, I was helped in fixing the human ethmoid by a few chalk marks placed upon the board by my professor, Dr. Elliott Canes [Coues?]. Simply a cross, to represent a front view of the vertical plate and crista galli, and the horizontal plate, and an oblong mass of white suspended from the arm of each cross, to represent the lateral masses. By comparing this image with the bone itself, a mental photograph was formed too simple ever to be forgotten. Having formed in this way a simple, durable image, it becomes an easy matter to modify it in detail. We may add the turbinal processes, the ossa plana, show their relation to the orbits and the frontal bone, and, having gone as far as convenient with the chalk, refer to more elaborate diagrams for details, and finally let the student finish by studying the bone itself. And how much more intelligently he can do it after we have prepared him in this way, by giving him a simple, durable, but plastic image as a basis, and by explaining to him the morphologic significance of the bone, as well as other interesting and practical facts relating to it. All the other bones may be treated in the same manner. The superior maxilla, for instance, may be built up on a triangular pyramid; the scapula upon a triangular prism, corresponding exactly to the triangular rod of cartilage from which it is developed; and even a bone of as variable form as a vertebra may be illustrated in such manner that a composite mental photograph of it is formed in which all of its variations are recognized, from the stunted tip of the coccyx to the typical dorsal vertebra, or the occipital bone, and even the other vertebral segments of the skull.

The ruder the drawing the better, for we do not now wish to impress the shape of the component parts, but the shape of the bone as a whole, and the relative position of its parts simply represented by masses of black and white.

There are, however, some things that can not be illustrated by even the most carefully prepared flat picture. Such things as the facial nerve in the aqueduct of Fallopius, the ventricles of the brain, the fissure of Sylvius, can not be drawn satisfactorily upon a plane surface. It is impossible to show the thing itself to a large class of students on account of its small size. In such cases we must resort to models large enough to be seen from all parts of the room. It will not answer to have a small model in the hands of each student, unless, with a pointer, we have a demonstrator stand over each student as the lecture proceeds. For teaching purposes I have a large, rough model of the left side of the brain, made of papier-maché, five feet long and yet light and easily handled. It is rough and apparently simple-looking, and yet I can show upon it the relative position and general shape of nearly every important part of the brain, both internal and external. I conceived the idea of making it mainly to show what I can not show in diagrams, the lateral ventricle, particularly its descending horn, the manner in which the pia mater enters to form the chorioid plexus, the velum interpositum, etc., and the fact that the five vesicles of the foetal brain remain distinct in the adult.

My conclusions are:

1. That we remember form, position, and relations by means of mental photographs.
2. That these are composite photographs.
3. That they may be easily modified from time to time, but can not be easily effaced or radically altered.
4. That these images are formed by the eye and understood through the ear.
5. That the power of mental photography varies in different persons, but may be cultivated in all, or nearly all, to a satisfactory point.
6. That the way to do this is to produce, first, a very simple impression, which, consequently, will be durable; and then more and more complicated images, that will not only coincide with and strengthen the first, but will, at the same time, add the necessary details.
7. That in doing this the primitive designs are best drawn upon the blackboard before the student's eyes; and that, afterward, a series of large diagrams should be used, or models in case diagrams are not satisfactory.

8. That the student is by these means taught how to appreciate and study Nature for himself in a calm, scientific, and observing manner.

An Army Medical Board will be in session in New York city, N. Y., during April, 1892, for the examination of candidates for appointment in the Medical Corps of the United States Army, to fill existing vacancies. Persons desiring to present themselves for examination by the board will make application to the Secretary of War, before April 1, 1892, for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from whence they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates, based on personal knowledge, from at least two physicians of repute as to professional standing, character, and moral habits. The candidate must be between twenty-one and twenty-eight years of age, and a graduate from a regular medical college, as evidence of which his diploma must be submitted to the board. Further information regarding the examinations may be obtained by addressing the Surgeon-General, U. S. Army, Washington, D. C.

The Medical Department of the Army consists of one surgeon-general with the rank of brigadier-general; one assistant surgeon-general, one chief medical purveyor and four surgeons with the rank of colonel; two assistant medical purveyors and eight surgeons with the rank of lieutenant-colonel; fifty surgeons with the rank of major; and one hundred and twenty-five assistant surgeons with the rank of first lieutenant of cavalry for the first five years of service, and of captain of cavalry subsequently until their promotion by seniority to a majority.

With the rank stated in each case the pay and emoluments of the rank are associated. The salary of each grade is a fixed annual sum payable monthly; but at the end of each period of five years of service the annual sum representing the pay of the grade is increased by ten per cent. until forty per cent. is added. After twenty years of service the forty per cent. additional continues to be drawn, but the further increase of the pay by ten per cent. additions ceases—*i. e.*, an officer, although he may have served twenty-five or thirty or more years, can, under existing laws, have no more than forty per cent. added to his pay proper by way of increase for length of service. The pay of a first lieutenant of cavalry, or of a medical officer during the first five years of his service, is \$1,600 a year, or \$133.33 a month. At the expiration of his five years of service he becomes, by virtue of that fact, a captain, and his pay is that of a captain of cavalry, \$2,000 a year, increased by ten per cent. for his years of service, *viz.*, \$2,200 annually, or \$183.33 monthly. At the end of his tenth year of service this rate of pay is increased by the service-addition to \$2,400 annually, or \$200 a month, and after five years more the service-addition makes his pay \$2,600 annually, or \$216.67 a month. If he continues in the rank of captain, at the end of twenty years of service his monthly pay becomes \$233.33; but about this time promotion to a majority is usually obtained, and a major's annual pay of \$2,500 with forty per cent. added, makes the monthly pay of the major and surgeon \$291.67. Subsequent promotion, investing the individual with the rank of lieutenant-colonel, colonel, and brigadier-general, augments the monthly pay respectively to \$333.33, \$375, and \$458.33. Compulsory retirement at the age of sixty-four years increases the rapidity of promotion to the younger men; and when retirement is effected, either by age or by the accidents of service prior to reaching the retiring age, the rate of pay subsequently drawn is seventy-five per cent. of the total salary and increases of the rank held by the individual at the time of his retirement. Thus, a major retired for broken health after twenty years' service draws seventy-five per cent. of \$291.67 a month; a colonel retired for age, seventy-five per cent. of \$375. The medical officer has the right of selecting quarters in accordance with his rank, and when stationed in a city where there are no Government quarters, commutation money, intended to cover the expense of house rent, is paid to him. The Government provides forage and stable room for the horses of the medical officer, and when he is traveling under orders the expenses of transportation are paid by the Quartermaster's Department.

Among the privileges granted to medical as to other officers of the army is that of leave of absence on full pay. The authorized leave

amounts to thirty days annually. This leave is not forfeited if not taken during the year, but is credited to the officer, who may thus accumulate a continuous leave of four months on full pay. If he desires to be absent for a longer period than four months, and the permission is accorded him, he is reduced to half pay for all time in excess of the four months or maximum of accumulated leaves of absence. Absence from duty on account of sickness does not affect the relations of the officer with the paymaster; he continues to draw full pay.

A commission in the Medical Department of the Army is an instrument which is good for life, premising conduct consistent with its retention on the part of its possessor; but it involves no contract which binds the individual to service for any given number of years. On the contrary, should the medical officer find on experience that civil life has greater attractions for him than that of the army, there is nothing to prevent him from at any time tendering the resignation of his commission.

A young medical officer on appointment is usually assigned to duty for a few months at some large post where there are other officers of his department, to afford him opportunity of becoming acquainted with the requirements of the Army Regulations and the routine duties of military life. After this he goes to some post west of the Mississippi River, where he serves a tour of duty of four years. An assignment in the East follows the leave of absence which is usually taken at this time; and in after years his stations are selected so as to give him a fair share of service at what may be called desirable posts as an offset to the time spent at less desirable stations.

Candidates for appointment to the Medical Corps should apply to the Secretary of War for an invitation to appear before the Army Medical Board of Examiners. The application should be in the handwriting of the applicant, should give the date and place of his birth and the place and State of which he is a permanent resident, and should be accompanied by certificates based on personal acquaintance from at least two persons of repute as to citizenship, character, and moral habits. Candidates must be between twenty-one and twenty-eight years of age (without any exceptions), and graduates of a regular medical college, evidence of which, the diploma, must be submitted to the board. The morals, habits, physical and mental qualifications, and general aptitude for the service of each candidate will be subjects for careful investigation by the board, and a favorable report will not be made in any case in which there is a reasonable doubt.

The following is the general plan of the examination:

1. The physical examination will be rigid; and each candidate will, in addition, be required to certify "that he labors under no mental or physical infirmity or disability of any kind which can in any way interfere with the most efficient discharge of any duty which may be required."

2. Oral and written examinations on subjects of preliminary education, general literature, and general science. The board will satisfy itself by examination that each candidate possesses a thorough knowledge of the branches taught in the common schools, especially of English grammar, arithmetic, and the history and geography of the United States. Any candidate found deficient in these branches will not be examined further. The examination on general science will include chemistry and natural philosophy, and that on literature will embrace English literature, Latin, and history, ancient and modern. Candidates professing proficiency in other branches of knowledge—such as the higher mathematics, ancient and modern languages, etc.—will be examined therein, and receive due credit for their special qualifications.

3. Oral and written examinations on anatomy, physiology, surgery, practice of medicine, general pathology, obstetrics, and diseases of women and children, medical jurisprudence and toxicology, materia medica, therapeutics, pharmacy, and practical sanitation.

4. Clinical examinations, medical and surgical, at a hospital, and the performance of surgical operations on the cadaver.

Due credit will be given for hospital training and practical experience in surgery, practice of medicine, and obstetrics.

The board is authorized to deviate from this general plan whenever necessary, in such manner as it may deem best to secure the interests of the service.

The board reports the merits of the candidates in the several branches of the examination, and their relative merit in the whole, according to which the approved candidates receive appointments to existing vacancies, or to vacancies which may occur within two years thereafter. At the present time there are fifteen vacancies to be filled.

An applicant failing in one examination may be allowed a second after one year, but not a third.

No allowance is made for the expenses of persons undergoing examination, but those who are approved and receive appointments are entitled to transportation in obeying their first order assigning them to duty.

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. Walter Wyuan, Surgeon-General of the Marine-Hospital Service, and published in the Abstract of Sanitary Reports for February 12th :

CITIES.	Week ending—	Population, U. S. Census of 1890.	Total deaths from all causes.	DEATHS FROM—

**The Function of the Hair-tufts in Man.**—In the January number of the *Journal of Anatomy and Physiology*, says the *Lancet*, Dr. Louis Robinson formulates a theory to account for the persistence in man of the tufts of hair usually present in the axillæ and over the pubes. These he imagines to be the persistent remnants of hair-tuft developed with reference to the clinging or grasping power of the young, and as a means of enabling them to cling to the parent when he or she, as the case might be, was not in a position to spare an arm without much imperiling the chances of escape or rendering movement difficult. Naturalists have observed that young apes hang beneath the body of the mother and sustain themselves by grasping the hair, and it is stated that certain male gibbons assist in carrying the helpless young. It is an interesting point that in these apes the period of immaturity is prolonged almost as much as in man. Other considerations which Dr. Robinson looks upon as supporting his theory are the appearance of the hair at puberty, its appearance in both sexes, and the fact that it often appears earlier and more plentifully on the female. It also exists in parts where the young of tree-climbing animals could attach their hands without danger of violent contact from obstacles, and Dr. Robinson has ascertained by measurement that in most cases the situation of the axillary and pubic tufts is within easy reach of the hands

and feet of infants when their limbs are extended, if the body of the adult is in the position taken by that of an anthropoid ape in climbing. The theory is no doubt ingenious; but objections to it readily occur. Dr. Robinson considers some of the most obvious of these, such as the existence of similar hair elsewhere and the sensitiveness exhibited by the skin when the hair in those parts is pulled. These, of course, are capable of being explained; but the theory would be very much strengthened if any example could be quoted of an anthropoid ape in which these tufts are actually used in the manner suggested by the author. Their development, if the theory is correct, must have been very much greater in his ancestors than it is in man at the present time to account for their persistence now, not only in the absence of any use for them for so many ages, but actually in spite of very considerable drawbacks to their existence, such as must exist in the friction to which they are exposed.

**The New York Academy of Medicine.**—At the next meeting of the Section in Obstetrics and Gynæcology, on Wednesday evening, the 25th inst., the following papers are to be read: Floating Kidney and Disease of the Generative Organs in the Female, by Dr. T. Schmitt; and Manual Rectification of Occipito-posterior Positions, by Dr. Egbert H. Grandin.

**To Contributors and Correspondents.**—The attention of all who purpose favoring us with communications is respectfully called to the following:

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Lectures and Addresses.

GASTRIC ULCER:

A CLINICAL LECTURE

DELIVERED AT THE WOMAN'S HOSPITAL OF PHILADELPHIA,

By FREDERICK P. HENRY, A. M., M. D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE IN THE  
WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA.

I wish to make this clinic both complementary and supplementary to the didactic course, and, with this end in view, I will endeavor to illustrate the latter by appropriate cases, and occasionally I will introduce a patient for the express purpose of enabling me to discuss a subject which otherwise would have to be postponed until the next winter's session.

The patient before you is one of the complementary cases—that is, her symptoms all point to an organ the diseases of which we have lately been studying in systematic detail. She has pain in the epigastric region shortly after eating, of a dull aching character, felt at times in the spine between the shoulder blades, and immediately relieved by vomiting. The relief which follows emesis is so prompt and so decided that the patient has acquired the habit of vomiting by irritating the fauces with her index finger. There is some tenderness in the epigastrium, only elicited by strong pressure, which is perhaps due to the fact that the layer of adipose tissue on the abdominal surface—the *panniculus adiposus*, as it is technically styled—is decidedly thick. It may also be due to the fact that the lesion which is the cause of this tenderness is seated on the posterior wall of the stomach.

I would specially direct your attention to the well-nourished condition of this patient. She is stout and florid, and, in fact, presents every external appearance of health. In speaking of gastric ulcer, you may recollect that I emphasized the fact that the external appearance, the so-called *facies*, of the sufferers from this disease was often such as to contradict the idea of an organic affection. This, of course, only obtains in the early stages of gastric ulcer, and you may also recollect my having mentioned that when in these cases failure of health occurred, it was apt to be sudden and decided.

From the fact of my having mentioned gastric ulcer, you have doubtless already surmised that I suspect this affection to be present in the case before us. Before, however, formally pronouncing a diagnosis of gastric ulcer, we must be careful to exclude other affections which resemble it. Cancer is out of the question. There is no symptom of stenosis of either orifice; there is no emaciation; on the contrary, the woman is stout and well nourished; there are no enlarged supraclavicular lymphatic glands; and, finally, as I hope to be able to show you presently, hydrochloric acid is abundantly present in the gastric secretions.

Let us next inquire as to the possible presence of chronic gastric catarrh. You are all familiar with the symptoms of this affection, for we have lately studied it in what I believe to be as thorough a manner as is possible with our present means of research. We have learned that while there is in

catarrh a sense of uneasiness and distention after eating, actual pain is rarely present, and when complained of is not described as being severe. The anorexia is also more complete than in ulcer. In fact, in ulcer the appetite may be good, being restrained for fear of the pain excited by its indulgence. Vomiting, when present, occurs at irregular periods, for example, before breakfast, and the vomited matters are mingled with mucus, or may consist solely of this substance. Symptoms other than pain, referable to the nervous system, are more common in chronic gastric catarrh than in ulcer, such as vertigo, insomnia, and hypochondria. The tongue is usually heavily coated, whereas in ulcer it is often remarkably clean. Finally, hydrochloric acid is often absent from the gastric secretions in cases of catarrh, especially when it is attended with abundant secretion of mucus.

Functional gastric disorder, the so-called nervous dyspepsia, is another affection that must be excluded before we can regard our patient as a case of gastric ulcer.

In nervous dyspepsia there are cructations of gas which are distinguished from those occurring in cases of catarrh by the fact that they are tasteless and odorless. Vomiting is rare. The appetite may be altogether absent or anorexia may alternate with periods of hyperorexia or bulimia. In catarrh the appetite is persistently absent. In nervous dyspepsia there is often pain in the stomach, but it occurs at irregular periods, not immediately after eating, as in ulcer, and, in fact, the pain may sometimes be relieved by eating. The tenderness in these cases is sometimes relieved by firm, steady pressure, whereas in ulcer the tenderness is in direct ratio to the degree of pressure.

There is one symptom to which I have not yet alluded, and which, if present, would settle this diagnostic problem offhand. This is hæmatemesis, which, of the three affections we have in mind—viz., ulcer, catarrh, and dyspepsia nervosa—is characteristic, not to say pathognomonic, of the first. Now, it is uncertain whether or not this patient has vomited blood. You may well inquire why there should be any uncertainty about the matter, and the reply is that recently streaks of blood appeared in the vomited matters, and that the slight hæmorrhage may have been due to the patient's efforts to relieve herself by vomiting. You will recollect my having told you that she excites emesis by thrusting her finger down her throat, and it is possible that in performing this manœuvre she may have injured the mucous membrane of the fauces. There are, however, no traces of any such injury.

In lecturing on gastric ulcer, I insisted on the fact that an ulcer can not be produced in a healthy animal by an injury of the gastric mucous membrane; but I said that if after such injury the gastric juice was rendered hyperacid by the occasional injection into the stomach of a solution of hydrochloric acid—for example, of the strength of five *pro mille*—the loss of substance, instead of rapidly healing, would degenerate into a typical round ulcer.

Again, ulcer will develop after an injury to the stomach of a chlorotic woman, even though the gastric juice be of normal acidity. Injury alone will not excite ulcer; otherwise this disease would be one of the commonest, for the

stomach is daily exposed to traumatism from thermal and mechanical causes.

For the production of gastric ulcer two things are necessary: 1. Traumatism. 2. A disproportion between the composition of the gastric juice and that of the blood.

This disproportion usually lies in the direction of hyperacidity of the gastric juice; but in a chlorotic woman whose gastric and other tissues are ill nourished, the gastric juice may be *relatively* hyperacid, even although the percentage of hydrochloric acid may be normal. In other words, the gastric tissues of a chlorotic female are less prone to heal after injury than are those of a person in good health—that is, they are less able to resist the corroding action of the gastric juice, and less able to institute the process of repair.

Our patient is certainly not chlorotic, and therefore if she is suffering from gastric ulcer we should expect to find a hyperacid condition of her gastric juice.

In the bottle in my hand there are two or three drachms of a perfectly clear, watery fluid, which is the filtrate of the matters vomited by this woman about an hour after eating. In this other bottle is a small amount of a yellowish liquor, which is composed of phloroglucin, two grammes; vanillin, one gramme; absolute alcohol, thirty grammes. This is the famous test for hydrochloric acid in the gastric secretions invented by Dr. Günzburg, of Germany, about which I have said so much in my lectures on the diseases of the stomach. It is undoubtedly the best test for the presence of hydrochloric acid in the gastric secretions, and is practically free from all sources of fallacy. I am, besides, especially interested in Günzburg's test because I believe I was the first to call public attention to it in this country. You will find it described by me in an editorial article in the *Medical News* for January 14, 1888, entitled Free Hydrochloric Acid in the Gastric Juice. The original article in which it was described by Günzburg appeared in the *Centralblatt für klinische Medicin* for October 1, 1887.

I will now proceed to apply this test in your presence. I pour two or three drops of the gastric filtrate into a watch-glass and add to it the same amount of the test solution. I then heat the mixture over a spirit-lamp, taking care not to boil it, and in a few seconds brilliant streaks of red appear in the edges of the fluid—*i. e.*, in its thinnest portions—which gradually spread until the bottom of the glass is entirely red. I advise you by all means to use a watch-glass for this test instead of the porcelain dish usually employed by chemists, because the watch-glass can be placed under the microscope and examined with a lower power by transmitted light. If this is done, it will be found that the red material which has formed on heating the mixture is largely made up of minute crystals which present a beautiful microscopic picture.

The object of heating the fluid was simply to drive off the water by evaporation, and thereby make the solution of hydrochloric acid more concentrated. This test is one of extraordinary delicacy, demonstrating hydrochloric acid in the gastric secretions when it is present in them to the extent of one twentieth of one per mille—0.05 pro mille.

I have now demonstrated the existence of free hydrochloric acid in the gastric juice of our patient, and, from the decided response to Günzburg's test, I am confident that it is present in undue amount. In cases of more doubtful diagnosis than the one we are studying we should go further in our chemical research and determine the percentage of hydrochloric acid in the fluid vomited or withdrawn from the stomach. This is readily ascertained by the well-known chemical process of titration. I did not attempt a quantitative analysis, because the amount of the filtrate was insufficient for that purpose.

I believe myself to be fully warranted in pronouncing a diagnosis of gastric ulcer in this case. Everything points in this direction: The sex—ulcer largely preponderating in females; the age, which is certainly not advanced; the character of the pain and its immediate relief by vomiting; the comparatively good state of the bodily nutrition; and, last, and most important, the abundant presence of hydrochloric acid in the gastric juice. These facts, I repeat, each one of which is significant, point unmistakably in the direction of gastric ulcer.

*Prognosis.*—We come now to consider the question of greatest interest to the patient—the prospect of recovery. Barring accident, this, under proper treatment, is good. We can not see this ulcer, and therefore know nothing concerning its area and its depth. It may have destroyed nothing more than the mucosa, while, on the other hand, it may have destroyed the submucosa and the muscularis, being prevented from perforation by the delicate serous covering of the stomach. Again, its base may be adherent to neighboring organs. Such considerations should make us guarded in our prognosis.

Hæmorrhage is another event that may occur at any moment.

The best safeguard against accident is the immediate institution of proper

*Treatment.*—The patient should be placed at rest. Bodily exertion of all kind should be strictly forbidden, for muscular movements might rupture protective adhesions, and so cause the fatal accident of perforation. Of all muscular acts, those concerned in vomiting are most injurious in these cases, and therefore pain should be relieved and muscular irritability allayed by opium or one of its preparations. Opium also accomplishes another important indication in obtunding the sense of thirst so often present in these cases. Nourishment should be administered for a few days by the rectum, but, in case of objection to this repugnant measure, the diet for a week at least should consist of peptonized milk mingled with lime-water. The latter substance is added for the purpose of neutralizing the excessive acidity of the gastric juice. Bicarbonate of sodium will accomplish the same result, but is not a safe remedy on account of the evolution of gas which follows its administration. Beef peptones and eggs may be gradually added to the peptonized milk, and by degrees a more liberal diet is permitted.

Medicinally, I can recommend nothing in addition to opium except the subnitrate of bismuth in large doses—say thirty grains three or four times daily. It serves to

neutralize acidity, and may, as some hold, form a protective coating upon the ulcerated surface. Benefit has apparently been derived from the use of nitrate of silver, but, in my opinion, such benefit is only apparent. It seems to me absurd to expect any local effect from nitrate of silver in these cases. The stomach is surcharged with acid secretions, which decompose this drug immediately. It might as well be decomposed beforehand by placing it in a glass of salt and water, and the patient directed to swallow it.

We will advise this patient to live on an exclusive diet of peptonized milk mingled with lime-water, in the proportion of half an ounce of the latter to four ounces of the former. We will keep her strictly quiet, in bed if possible; and we will order, besides, half a drachm of subnitrate of bismuth every four hours. In addition we will allay pain and vomiting with suitable amounts of morphine. For the latter purpose, one eighth of a grain daily may suffice, while, on the other hand, one grain in divided doses may be necessary.

If these directions are carried out, I hope to present her to you, on some subsequent occasion, much improved in every respect.

## Original Communications.

### THE

### RADICAL CURE OF CONFIRMED FLAT-FOOT.\*

BY ROYAL WHITMAN, M. D., M. R. C. S.,

ASSISTANT SURGEON TO OUT-PATIENTS,  
HOSPITAL FOR RUPTURED AND CRIPPLED.

THE term flat-foot is in some respects an unfortunate one, in that it does not correctly describe the affection, of which the important condition is abduction, and because most physicians and patients understand by flat-foot an inherited weakness which is to be endured or relieved by braces rather than to be actively treated and permanently cured.

I propose, therefore, to call your attention to some of the predisposing and exciting causes of weak foot, its progressive character and results, and to explain somewhat in detail the treatment which has been very successful in the cases falling under my observation.

Clinically, without attempting to enumerate all the varieties of this very common affection, cases may be divided into groups.

1. The cases known as weak ankles in weak or rhachitic children, or accompanying slight knock-knee.

2. The long weak foot seen in adolescence. These children are usually brought on account of prominence of the internal malleoli which are thought to be "growing out." The symptoms are awkwardness in walking, with fatigue on any overexertion. Here we find a prominent scaphoid, slight abduction and limitation of the movement of adduction, but usually no pain or tenderness on pressure. These cases are of importance, because in later years,

under the increased work to which the feet are subjected, they may develop into the most confirmed and painful deformity.

3. Weak feet in older subjects, particularly women who are obliged to stand much of the time. In these cases the pain is very severe, but ceases when the feet are not used. There is usually but little spasm of muscles or limitation of motion—that is, the feet can be easily replaced in proper position, but are markedly flattened when weight is borne. There is great sensitiveness to pressure on the painful points, and often redness and swelling. This variety is very common, and is the form that most physicians associate with the term flat-foot.

4. The most interesting and important class with which this paper is chiefly concerned, usually seen in young adults. Here we find marked deformity and muscular spasm, so that the foot is quite rigid and can not be replaced in normal position. The arch is more or less flattened, but the important condition is the abduction—that is, when the feet are placed side by side there is a wide interval between the two great toes which the patient can not lessen, the power of adduction being limited or lost. In these cases the disability is very great, and the pain persists even when the feet are not actively used.

5. True flat-foot, or pes planus, which may be actually inherited or the result of rhachitis in infancy. There are often no symptoms, and the condition need only be considered when pain is present.

It must be borne in mind that these varieties blend with one another, and that pain and discomfort do not in any sense correspond with the degree of deformity.

Flat-foot is considered by the writer as an acquired partial dislocation, caused by a disproportion between the weight to be sustained and the strength of the supporting structures. This broad definition includes everything that may weaken the foot or place it at a disadvantage in the performance of its functions, such as improper shoes and their consequences—corns, bunions, ingrown toe-nails, deformities of the toes, etc.—inproper attitudes in activity and rest, local injury, or acquired or inherited weakness or disease; while overweight may mean long standing, laborious occupation, or simply increase in body weight. The examination of a large number of sufferers from flat-foot, a considerable proportion of whom were young and vigorous adults whose muscular development enabled them to engage in the most laborious of occupations, has confirmed me in the belief that the breaking down of the arch, in this class at least, is not the result of intrinsic weakness of muscles,\* or primary relaxation of ligaments,† or congenital deformities of bone,‡ or because there was some peculiar disease of cartilage,§ or primary muscular paralysis, atrophy,|| or spasm,^ or because the patient had worn high heels ◇—according to the various theories that have been advanced by writers on the subject—but because the feet, originally sufficiently strong, had been placed at a serious disadvantage in the performance of their functions.

As a clear understanding of the causes of flat-foot is

\* Read before the Harvard Medical Society of New York, October 3, 1891.

\* The usually accepted theory.

† Tillaux and Lefort.

‡ Stokes. § Gosselin. || Sayre. ^ Duchenne. ◇ Mayo-Collier.

essential to a proper apprehension of its successful treatment, I shall try to explain what these disadvantages are and how they may be overcome and avoided.

*Attitudes.*—The attitude of adduction is the strong position, the attitude of abduction the weak one.

The elastic walk of a barefoot child illustrates the first, a soldier presenting arms the second position. In the first instance the feet are under the control of the adductor muscles, and the ligaments are relieved from strain; in the second, or attitude of rest, the ligaments bear the greater part of the weight. Thus adduction, which implies muscular activity, is the most favorable attitude for supporting weight; abduction, the most unfavorable.\* A glance at the anatomical structure of the foot will make this clear. In a general way it may be divided into two arches—an outer or strong arch, solidly braced and usually in direct contact with the sole of the shoe, composed of the os calcis, cuboid, and two outer metatarsals; and an inner and weaker arch, made up of the os calcis, astragalus, scaphoid, three cuneiform and three inner metatarsal bones, directly under control of the adductor muscles, whose strength and activity are essential to its support. Again, the astragalus is perched upon the os calcis, “like a lady on horseback,” at a point somewhat internal to its base, so that the weight of the body transmitted through it tends to tip the os calcis over to the inner side, allowing the astragalus to slip downward and inward. A certain amount of inward rotation of the astragalus as the foot broadens and flattens under weight is normal,<sup>8</sup> but before it becomes excessive the strong adductor muscles contract, the great toe is braced to resist the lowering of the arch, and the weight is thrown toward the outer side of the foot.

The more the feet are habitually turned outward in standing and walking, the greater the strain upon the arch; the more they are turned inward toward the line of the walk, the greater the protection of the weaker side of the foot. To illustrate, if the feet in walking are pointed straight ahead in the line of the walk, flexion and extension at every step, or muscular activity, is essential, because the toes, being in front of the body, must be walked over, and the weight of the body lifted at every step by muscular contraction. If they are turned outward, the weight is first thrown upon the heel, then directly upon the weakest part of the foot, and we have the passive, inelastic walk of the weak, aged, and flat-footed. If the foot is to be actively used, it is essential that its component parts should be in healthy condition; thus it will be understood how corns, bunions, ingrown toe-nails from improper shoes, weakness from injury, or the result of gout or rheumatism, may make active flexion of the foot painful so that it is avoided by turning the toes outward. I have also shown in a former paper that the faulty position of the feet is habitual in a very large proportion of individuals.† Muscles are weakened by disuse and improper shoes, and under the influence of overwork, injury or disease, overstrained arch and later

flat-foot may develop. To illustrate this point Fig. 1 and Fig. 2 have been drawn from life. Fig. 1 represents the passive walk with eversion of the feet, the weight of the body falling on the inner or weaker side. Fig. 2 shows the proper attitude, the muscular activity and protection of the arch being very apparent. The subject of this paper being the treatment of confirmed flat-foot, I shall briefly describe

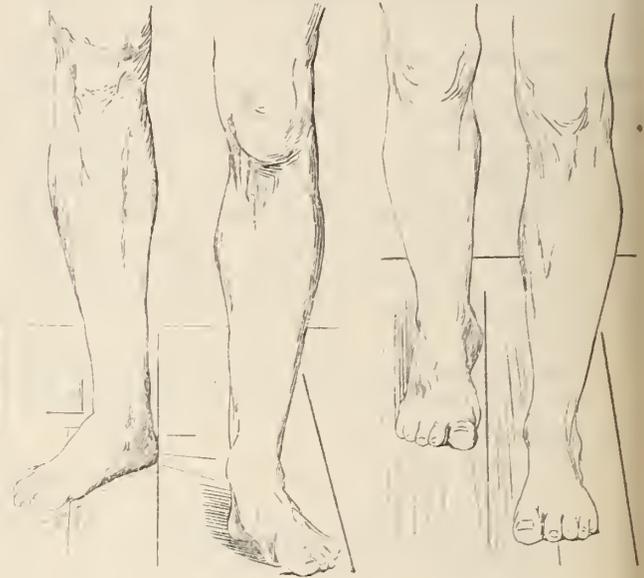

FIG. 1.

FIG. 2.

the anatomical conditions which may be present in such a case, with its symptoms, and then the steps by which a radical cure may be accomplished.

In confirmed flat-foot we shall find an exaggeration of the condition before indicated: the os calcis tipped over to the inner side and rotated inward; the astragalus rotated inward and dislocated downward and inward; the entire fore-foot, everything in front of the medio-tarsal joint, thrown downward and outward; the foot is as it were broken in the center. The arch has to a great extent disappeared; there is a marked projection on the inner side caused by the displaced astragalus and scaphoid, while the foot is lengthened and broadened in shape.

The overworked peronei muscles are in a state of spasm or are actually shortened, and resist any attempt at reduction of the deformity. The adductors have lost their power, and, in addition, there is usually a loss of function of the toes with callosities and corns. Often there is more or less swelling of the feet with excessive sweating.

Dissection\* shows weakened and atrophied muscles, overstretched ligaments, changes in the bones with the formation of new facets, and other evidence of the chronic inflammation which has accompanied the gradual progression of the affection. Such changes are, however, the result of many years of neglect, and illustrate the importance of early diagnosis and treatment.

The affection is easily recognized. Persistent pain,

weakness, and discomfort about the arch of the foot, increased by standing or walking, particularly on going up or down stairs, which necessitates an extra exertion of the affected joints, with tenderness on pressure at the junction of the astragalus and scaphoid, are perhaps the earliest symptoms. In some cases the arch may appear perfectly normal, while in others the foot is entirely flat.

The usual symptoms, some of which are always present, are as follows:

1. The peculiar inelastic walk, the weight being thrown upon the heels, the feet turned outward to avoid activity; as patients express it, "the feet have lost their spring."

2. The deformity—the flattening of the arch, and the projection on the inner side of the foot, when weight is borne—a deformity which later becomes permanent, from muscular spasm, contraction, and shortened ligaments, with inflammatory adhesions between the bones.

3. Pain in the feet, with local tenderness on pressure, referred to the following points in order of frequency:

1. The astragalo-scapoid junction.
2. Below the external malleolus.
3. The dorsum of the foot.
4. The center of the heel.
5. Beneath the great toe joint.

The pain is often reflected up the inner or outer side of the leg to the knee or hip.

4. Extreme stiffness of the feet after sitting, or on rising in the morning, or cramps at night in the feet or calves, symptoms usually associated with the more advanced cases, indicating, I believe, beginning changes in the bones, with the formation of new facets. To illustrate, two patients have recently consulted me who refused to sit down in my office because the effort to stand was so painful after the momentary relaxation of the muscular tension.

In considering the question of early diagnosis, the intermittence of symptoms should be borne in mind; thus, a weak foot when subjected to overstrain becomes painful. After a few weeks' rest the pain ceases, to recur several months later under similar irritation. There are, too, rheumatic symptoms in a weakened foot; the pain, often accompanied by redness and swelling, is worse in damp weather, or the affection may be the result of weakness following true rheumatic inflammation, although this is comparatively rare. As flat-foot is so constantly mistaken for rheumatism, it would be well to remember that rheumatic inflammation is rarely confined to one member or joint, that persistent pain in the feet is almost always of local origin, and that local treatment for local pain and deformity is always in order, while medicinal treatment, except for the rest of the affected parts, which may be advised, is worse than useless, as it postpones the recognition and proper treatment of the true affection. If this proposition, that persistent local pain demands local examination and treatment, were accepted, many sufferers might be relieved from years of pain and discomfort.

In considering the treatment of a case of flat-foot, the important question is this: Can it be replaced in proper position? If it can—that is, if its movements are free and unembarrassed, not limited by muscular spasm or in-

flammatory adhesions—the treatment is very simple. An efficient support, a proper shoe, an avoidance of faulty positions, with exercises for strengthening the weakened muscles, will at once relieve the patient. If, however, the reduction of the deformity by manipulation is impossible, it should be treated as any other dislocation should be—adhesions should be broken up and the deformity reduced. This variety, which I have included in the fourth class, is the most interesting and important, because the patients are usually young adults; the deformity is extreme; the affection rapidly progressing; the patients are almost completely disabled; the symptoms are so urgent that they are very amenable to treatment, and the results are most satisfactory. Excessive muscular spasm and rigidity in a young person I have come to look upon as a very favorable indication, as it shows muscular strength and integrity of bone—the same distinction that one might make between a recent dislocation with the accompanying pain and the passive acceptance of the situation in a displacement of long standing. A radical cure is possible in all recent cases of flat-foot, and relief of pain and, to a great extent, of deformity may be assured in every case.

Some writers hold out the forlorn hope that when the deformity is complete—that is, when the astragalus rests upon the sole of the shoe—pain ceases. I need only mention the fact that I have treated patients after twenty years of continuous and increasing discomfort. The treatment of this class of cases is conducted on the following principles:

1. Forceful reduction and overcorrection of the deformity.
2. A temporary support to prevent relapse.
3. A proper shoe.
4. Manipulation to stretch contracted and shortened tissues.
5. Exercises to strengthen weakened muscles.
6. A re-education of the patient in the proper manner of walking and supporting weights.

In brief, the application of the simplest surgical princi-

ples. Under ether, the foot is forcibly moved in all directions to break up adhesions, and is then forced into a position of extreme adduction or equino-varus and retained there

by a well-padded plaster bandage. Although great force is sometimes used, the after-symptoms are usually slight, and the patient, if he desires, is allowed to walk about on the plaster bandages on the following day. In about a week, or earlier, if there is no pain in the feet, the bandages are removed and plaster casts are taken for the support which is to be used.

Casts are easily and quickly made in the following manner: Seat the patient in a chair; in front of him place another chair of equal height; on it lay a thick pad of cotton batting and cover it with a square of cotton cloth. Put about a quart of cold water into a basin with a tablespoonful of salt; sprinkle plaster on the surface, stirring until the mixture is of the consistence of thick cream, then pour it upon the cloth. Flex the patient's knee and allow the outer side of the foot, previously oiled, to sink into the plaster, raising the edges of the cloth until rather more than one half the foot is covered. When this is hard, spread vaseline on its upper surface, and, having mixed a smaller quantity of plaster, cover the exposed surface of the foot; the toes need not be included. When hard, the two halves are removed and their inner surfaces oiled. They are then bandaged to one another and the interior filled with plaster of the same consistence as before. When the outer shell is removed, we have a reproduction of the foot ready for further manipulation. This consists in changing the cast with the exercise of a certain amount of judgment, so that it may resemble a perfect foot—that is, to scrape away the projection on the inner side if any remains, and to deepen the inner and outer arches. Several years ago I was in the habit of making the brace on an actual reproduction of the foot, but experience showed that it was possible, by the treatment to be described, to still further overcome deformity which could not be corrected by the forcible reposition under ether. When completed, the casts should stand squarely on the table with no inclination to either side; they are then sent to the founder to be reproduced in iron.

The feet are, if the case is one of long standing, again placed in adduction and the plaster bandages reapplied. No anæsthetic is necessary, as the previous overstretching, with the subsequent rest, has to a great extent removed the resisting muscular spasm. In from one to three weeks, according to the judgment of the surgeon, the bandages are removed and active treatment begun. The flat-foot on which forcible over-correction has been performed is now, although in good position, stiff, and all its movements are restricted and painful, and if the patient is allowed to go about without support and further treatment, a recurrence of the deformity is inevitable.

The subsequent treatment is carried out with the aim of regaining free and painless movement in every direction, particularly in adduction. The foot is first immersed for ten minutes in hot water, afterward vigorously massaged, especially about the dorsum, and is then slowly forced into a position of adduction. This manipulation, first described by me in the *New York Medical Journal* of October 11, 1890,\* has gradually assumed greater importance, and is

now considered an essential for the successful treatment of the affection. It is conducted as follows: The patient is seated in a chair; the surgeon stands in front of him. Let us suppose that the left foot is to be adducted or, as patients express it, twisted. The surgeon places the foot between his knees; his left hand encircles the heel, the fingers grasping the projecting os calcis and tendo Achillis; the ball of the palm lies against the mediotarsal joint on the inner aspect of the foot; the right hand grasps the outer side of the fore-foot and toes; then by steady pressure of the thigh muscles the fore-foot is forced inward over the fulcrum formed by the projecting palm which lies upon the left knee, the fingers holding the heel steadily in place. This inward twisting is at first resisted by a mixed voluntary and involuntary muscular spasm, which gradually gives way under steady pressure. When the limit of adduction has been reached, the foot is firmly held until all pain has subsided, when the patient is instructed to make voluntary movements while the foot is in the corrected position, flexion and extension of the toes, and to contract the flexor muscles of the foot. The foot is then released, and twenty minutes of voluntary exercise follow, and at intervals during the day the patient, by active muscular efforts and passive motion, constantly works to one end—namely, to regain the lost power of adduction—while once daily the inward twisting is performed by the surgeon. Under this treatment the pain and stiffness rapidly disappear, and the foot constantly assumes a better position. The results that can be attained by this treatment persistently carried out, even in cases of long standing and apparently hopeless deformity, are surprising. I wish to call your attention to the fact that forcible *over-correction* followed by persistent passive stretching of contracted tissues is quite different in principle from the simple forcible correction of deformity with indefinite retention of the feet in plaster and silicate bandages, as practiced by Roser, Lorenz, and Smith. Meanwhile the brace is made of thin steel.\*

It is molded on the iron cast while hot, and is then tempered so that it is unyielding under the weight of the body.

Its shape may be seen in the diagrams (Figs. 5, 6, and 7). A broad internal upright portion covers the

FIG. 5.—A, the astragalo-scapoid joint.

astragalo-scapoid joint, the weak point of the foot; a molded arm reaches from the center of the heel to a point just behind the bearing surface of the ball of the

great toe; an outer arm passes beneath the os calcis and cuboid bones, and upward slightly on the outer aspect of the foot, which is thus held firmly in the brace, and can not slip away to the outer side, as is the case with braces which depend upon the shoe to hold the foot in position. As the patient is instructed in the proper walk, he throws his weight first on the outer side of the foot, thus pressing the external arm down against the sole of the shoe, a movement which at the same time causes the internal projection to press more firmly against the inner side of the foot. This pressure tends to turn the fore-foot inward, relieving the arch from weight. In addition, this brace differs in the following points from those with which I am familiar, in that it is an accurate adjustment to a cast of the corrected foot; that it, by the inward flange,

FIG. 6.—C, the great-toe joint; D, the center of the heel.

prevents abduction, a movement which precedes the lowering of the arch; that the brace is complete in itself and does not depend upon the shoe to prevent deformity; that it is not

FIG. 7.—B, the calcaneo-cuboid joint.

in any way attached to the shoe, but retains itself in proper position—it may thus be changed from one shoe to another, and may be kept clean and free from rust; that it allows the foot to rest upon its natural supports, the heel and the ball of the foot, provides support only to the weak points, and does not in any way restrict normal motion and activity, which are to be encouraged by insisting that the patient shall assume the proper attitude in walking. This brace is not a spring; it is inelastic, as it is intended to hold the foot in normal position, not to allow a recurrence of previous deformity. Finally, it is comfortable; the painful pressure on the sole of the foot, often complained of when simple arched supports are used, being absent.

It is nickel-plated or tin-plated and is then japanned. No covering is used, and, as it fits the foot perfectly, its presence in the shoe can not be detected.

The shoe to be recommended is one of the Waukenphast pattern, with a sole broad enough to support the foot, having an inward twist to allow room for the great toe. In advanced cases of flat-foot I usually build up the inner side of the sole after the method known as Thomas's, in order to

throw the weight more to the outer side while the foot is still weak. The patient is then allowed to go about his usual occupations, no restriction being placed upon walking, provided the proper attitude, with but little divergence of the toes, is assumed.

The entire treatment described has consumed on an average three weeks. Daily exercises are still continued with the stretching until the movements of the foot are absolutely free and unembarrassed. One of the best gymnastic exercises for strengthening the feet is to raise the body on the toes twenty or thirty times, morning and night, as recommended by Ellis (*Lancet*, September 26, 1885). It will, however, be remembered that the best possible exercise is a proper walk. In an ordinary case the braces can be dispensed with in about six months, when a cure may usually have been accomplished, although all symptoms have disappeared long before.

The limits of this paper have simply allowed me to outline this method of treatment; many aids in gymnastic and local treatment will suggest themselves. The essentials for entire success are a complete reduction of deformity, a complete recovery of the lost power of adduction, an increase in muscular strength and activity, and an avoidance of improper attitudes in standing and walking. The success that follows persistent treatment of confirmed flat-foot is most gratifying, and my experience justifies me in asserting that no affection of equal importance can be so easily relieved and permanently cured.

In conclusion, it may be well to mention the operative treatment of flat-foot. The operation described by Golding Bird,\* Ogston,† and, with modifications,‡ by various others, consists essentially in destroying the mediotalar joint by producing an ankylosis between the astragalus and scaphoid bones. I have not seen a sufficient number of cases to judge of its merits; the few that I have seen presented a stiff but useful foot with a partial relief of pain and deformity. Most of the reported operations have been performed on children and young adults, the most favorable class for cure with preservation of normal joints, a result which must be vastly superior to any relief that may be obtained by an operation which aims at the destruction of the most important joint of the foot. The essential difference between the two methods of treatment is this: The one recognizes the fact that a foot subjected to the predisposing and exciting causes outlined may, by slow progression, reach a stage of extreme deformity; and that the affection is curable by a reversal of the conditions under which it developed. The other assumes the impossibility of cure and endeavors to relieve the symptoms by substituting an ankylosed joint for muscular strength and activity. The first method requires patience, persistence, and the intelligent co-operation of the patient. The second requires nothing but the ability to perform a cutting operation. There is, however, a class of patients in most destitute circumstances, with no shoes, no money, no homes. Here

\* *Guy's Hospital Reports*, 1882.

† Ogston. *Lancet*, January 26, 1884.

‡ Hare. *Lancet*, November 9, 1889.

hospital treatment is a necessity, and hospital treatment for flat-foot at least implies an operation. For this class the operation—and, in my opinion, the only cutting operation which should ever be performed for flat-foot—is the supra-malleolar osteotomy of Trendelenburg,\* first performed here by Dr. Willy Meyer.† The object of the operation is the production of artificial bowlegs, thus throwing the weight off the arch to the outer side of the foot. Dr. Meyer's results have been very satisfactory. The disadvantages of the operation are the time that is necessary for consolidation of the divided bones and the very noticeable bowing of the legs, which would preclude its use in patients of more æsthetic temperament. I should suggest that the breaking up of adhesions and over-correction of the deformity would be a useful preliminary to the operation. Finally, I may again urge the importance of an early recognition and intelligent treatment of this affection which has such an important influence on the future prospects of the young, and in later years may reduce the sufferer and those dependent on him to the most extreme destitution.

126 WEST FIFTY-NINTH STREET.

#### A CASE OF INTRINSIC EPITHELIOMA OF THE LARYNX. †

By MORRIS J. ASCH, M. D.

R. G., aged seventy years, came to me in the autumn of 1889, complaining of hoarseness. He had no cough or any evidence of disease beyond the interference with his voice. He was a hale, hearty man, living much in the open air, hunting during the winter in the South, and yachting and devoting himself to the care of his country place in the North during the summer. He was a retired physician, and consequently able to describe his symptoms with accuracy. He complained only of the hoarseness, which was brought to his notice by his inability to call his dogs as formerly, and which he attributed to having taken cold. There was no pain, dyspnoea, or dysphagia. A laryngoscopic examination was difficult, owing to the extreme sensitiveness of the pharynx, but the application of an eight-per-cent. solution of cocaine soon produced tolerance. Even then, owing to the thickened and depressed epiglottis, an examination was difficult, but the mirror revealed the ventricular band of the left side irregular in outline and swollen to such a degree as to conceal the vocal cord of that side. The left aryteno-epiglottic fold was unchanged; the mucous membrane darker than normal, smooth, and without ulceration. The subglottic region was invisible, owing to the narrowing of the rima glottidis. The laryngeal image was that of a chronic hypertrophic laryngitis. A few topical applications were made with apparent relief of the hoarseness, and the patient left for his Southern home. In the spring of 1890 he returned. He was full of life and vigor, was perfectly well in every way, except that the hoarseness persisted. The larynx presented nearly the same general appearance as at the previous examination, except that the deposit in the ventricular band of the left side had increased and there was some swelling in that of the right side. There was no dyspnoea or pain, and the local applications were con-

tinued and seemed to give relief; but the continuance of the swelling for so long a period and the absence of any improvement after treatment caused me to apprehend the existence of malignant disease, although there was nothing in the condition of the patient or in the appearance of the part to warrant any such diagnosis with certainty. There was no soreness over the larynx, though the thyroid cartilage was slightly enlarged; neither was there any glandular enlargement in its vicinity. In November the patient, on his way South, returned again to the city, with no change in his condition or in the appearance of the larynx. He was cheerful, and sure that a mild climate would bring him back in the spring quite cured, although he was warned of the probable gravity of his case.

In March, 1891, he presented himself unexpectedly at my office, showing evidence of great suffering. His voice was almost extinct, his breathing difficult, and he was weak and emaciated to a degree. The increasing dyspnoea had compelled him to return North thus early in order to obtain relief. Examination showed the lumen of the larynx almost entirely occluded by an irregular swelling from both sides, the merest chink remaining to give passage to air, which found its way between the irregular prominences on either side; no ulceration of any kind was visible, and the appearance was that of an irregular swelling with a smooth surface. There was a small, enlarged submaxillary gland on the left side. The patient was at once informed of the gravity of the situation and an immediate tracheotomy advised. This he declined, although the danger of delay was pointed out to him, until he could terminate certain important business affairs; to this I was obliged reluctantly to consent, though I feared that a sudden termination might occur at any moment. The dyspnoea was so extreme that comfort in respiration was only secured when the patient was at rest. He visited me daily, always refusing to permit the operation until the morning of April 5th, when he presented himself with his respiration embarrassed to such a degree that there was no longer any question as to delay. He was taken to the New York Eye and Ear Infirmary, where, in the presence of Dr. C. T. Poore and the house staff, I performed tracheotomy. The dyspnoea by this time was so intense that I deemed it unsafe to administer an anæsthetic, and I injected a few drops of a two per-cent. solution of cocaine over the proposed line of incision, with the effect of rendering the parts insensible to pain and enabling the patient to undergo the operation without inconvenience. It was found impossible to extend the neck to any degree, as, on attempting to raise the shoulders, suffocation immediately ensued, and in consequence the operation was rendered extremely difficult, the cricoid cartilage being nearly at the level of the episternal notch. The first incisions, which were almost bloodless, having been made, the trachea was opened through the upper rings. Owing to its ossification, a partial resection had to be made to permit of the introduction of the tube, the relief from which was immediate. The patient did well for some days, when a severe attack of grippe—which was prevalent at the time—caused him considerable discomfort, and from the effects of it he did not recover for three weeks. Immediately after the operation deglutition was painful, but this soon passed away, and on April 26th, when he left the infirmary to return to his lodgings, he could swallow with perfect comfort. His only annoyance next to his weakness, which persisted, was the frequent clogging of the tracheal tube with a sticky mucus, which required constant attention to prevent untoward results. As his neck was extremely thin, it was thought that perhaps this might be caused by irritation resulting from the impinging of the tube on the posterior wall of the trachea, so a new one was ordered, having a shorter horizontal member than the one in use, and with a curve of a quarter of a circle. This tube partially relieved the

\* *Archiv für klin. Chir.*, xxxix, 4.

† *N. Y. Med. Journal*, May 24, 1890.

‡ Read before the American Laryngological Association at its thirtieth annual congress.

symptom, but not entirely. About the middle of May the expectoration was streaked with blood, which, as the lungs were perfectly sound and the external wound in good condition, gave rise to the fear that the disease might be spreading downward and ulcerating. Early in June the patient, having gained strength, was removed to his country seat on the North River, where for a time he did well. In a few weeks, however, spasmodic attacks of dyspnea came on, which he attributed to plugs of solid mucus occluding the tube, and which he relieved by removing the tube and coughing the mass through the opening in the trachea. Desirous to have my opinion as to the cause of the trouble, he took passage on the night of the 11th of July on a night boat on the Hudson River. Soon after his embarkation a severe attack of dyspnea came on, which his attendant was unable to relieve. A thick fog prevailing at the time prevented the captain of the boat for several hours from making a landing to obtain the services of a physician, and when finally medical aid came, he was dying from exhaustion.

*Autopsy*—Permission having been granted to examine the larynx only, the condition of the other organs could not be ascertained. The body was thin, but much less emaciated than before the operation. Externally, the opening of the tracheal wound was in good condition, no granulation or diseased tissues being observed, nor was there any trace of disease external to the larynx. The larynx and three rings of the trachea were removed from the body. On inspection from above, the lumen of the larynx was seen to be entirely occluded by smooth irregular masses springing from the ventricular bands of either side. On dividing it posteriorly in the middle line and exposing the interior of the larynx, the cartilages of which were ossified, these growths

were found to be in contact and to fill up the entire cavity. The left ventricular band was enormously swollen and the vocal cord of the same side ulcerated. Extending downward from its inferior border to a point level with the middle of the tracheal opening and covering the entire laryngeal wall of the left side was a papillary mass ulcerated on its lower portion. On the right side the ventricular band was infiltrated, but not to so great a degree as the left. The vocal cord was thickened, and below it a mass of diseased growth extending nearly to the lower border of the thyroid cartilage. Just to the right of the median line at the base of the cricoid cartilage and above the upper margin of the tracheal wound was a globular pedunculated tumor of the size of a large pea. There was no erosion or growth below the level of the tracheotomy wound. The submaxillary gland on the left side was enlarged. The specimen was sent to Dr. R. G. Freeman for examination, who made the following report:

The specimen shows considerable swelling of the glottis and upper part of the larynx. Below the vocal cords, on the anterior wall of the trachea, a growth five sixteenths of an inch in diameter and three sixteenths of an inch in height projects. Just below this is the artificial opening due to tracheotomy. The upper lip of the opening is somewhat thickened. The tumor involves all the upper portion of the larynx and the anterior wall

of the lower portion. Specimens were taken for examination from the posterior and lateral walls of the glottis, and from the growth from the anterior wall below the cords.

*Microscopic examination* showed the tumor to be an epithelioma. The cells are grouped in a reticular arrangement with a varying amount of stroma. In places they are arranged in concentric masses, forming epithelial pearls. In some parts there is an extensive production of spheroidal cells. There is some necrosis on the surface. The mucous glands are inflamed and some of these ducts are occluded by inflammatory changes.

There are certain points in this case which make it of special interest. *First*, the absence for so long a period of positive signs of malignant disease; and, *secondly*, the nature of the irritating cause producing the spasmodic attack which finally destroyed life.

The first point is accounted for by the fact that the case, being one of *intrinsic* cancer, was naturally slow in growth. There was no external manifestation of the disease, unless the slight glandular swelling could be so considered; nor was there any evidence of infection of any other organ. There was a thickening of the mucous membrane of the ventricular bands with infiltration of the muscles and loss of motion, which swelling forbade a view of the subglottic lesion, which, if visible, might probably have revealed its true nature; but there was no ulceration, no lancinating pain in the ear or elsewhere, no reddened base, nor any certain sign of malignant disease—only swelling and dysphonia; and in this case a fragment removed for microscopic investigation might have proved deceptive, for the sections taken from the upper portion of the ventricular band showed evidences of inflammatory action more markedly than of epithelioma. Even at the last, when the increasing stenosis rendered operation necessary, there was no absolute proof of cancer. This could only be deduced from negative data by clinical experience. Tubercle and syphilis being excluded, there could be nothing to account for the condition but malignant disease.

From the point of view well taken by Butlin, that intrinsic cancers not only differ essentially from those of extrinsic origin by their limitation to a circumscribed area, but, being less actively malignant, are less likely to recur, this case would seem to have been a favorable one for excision, were it not for the advanced age of the patient warranting the opinion that tracheotomy would afford relief during the probable term of his natural life. Thyrectomy was out of the question, as the ossified state of the cartilage forbade the idea that the larynx could be sufficiently dilated to permit of a thorough operation being performed. In the treatment of the case, pyocyanin blue was employed locally and internally, but without any apparent effect. Taken internally in doses of three grains, it produced vomiting and could not be continued.

The cause of the paroxysms of dyspnea is obscure, unless it can be attributed to the globular mass projecting into the windpipe, producing them as asthma is caused by similar proliferations into the upper air passages. I attribute the fatal termination immediately to cardiac weakness, the result of the grippe with which he was attacked after the operation.

## INTUBATION FOR THE RELIEF OF STENOSIS IN TUBERCULAR LARYNGITIS.\*

By F. E. HOPKINS, M. D.

THE following case is presented, not only because of some points of interest which it may have in itself, but because it involves the suggestion of intubation as a substitute for tracheotomy in stenosis due to tubercular disease of the larynx:

Mrs. B., American, of German parentage, aged thirty-nine, seventh in a family of eleven children. Four sisters are living, and all are of the stout Germanic type, their ages ranging from thirty to forty-five years; all in good health.

A sister died in Germany, aged forty-six; cause unknown. A brother died of pneumonia in October, 1890, aged thirty-six. The remaining children died in infancy. The father is living and in good health at the age of seventy-eight. The mother died at fifty-three of typhoid fever. The grandparents, both paternal and maternal, reached a good old age, dying at ages ranging from seventy-four to eighty-eight. Of the uncles and aunts, one, an uncle, died at the age of sixty-five of peritonitis. A maternal uncle died of "consumption" at the age of twenty-five. An aunt died at seventy-seven, her twin sister six months later; causes unknown. An aunt is living and in good health at the age of sixty-seven.

It is thus seen that the woman's history is exceptionally good for a hospital patient, and it helps to account for her powers of resistance against the disease from which she suffers.

Mrs. B. always enjoyed good health till November, 1885, when she had an attack of pneumonia. The attack was not a severe one, but was followed by a laryngitis and a cough, which continued till she came to the Manhattan Hospital in June, 1886. During this interval from November to June she received no special treatment, and the symptoms had increased in severity.

Through the kindness of Dr. Charles H. Knight, under whose care this patient was when she first came to the hospital, I am able to present the following notes of her condition then:

At the time this patient first came to the Manhattan in 1886 her general condition was good. She had but little cough, and that without expectoration. By physical examination no evidence of pulmonary disease could be discovered. Her object in coming to the clinic was to get relief from hoarseness, which had annoyed her for several weeks.

On examining the larynx with the mirror the following conditions were seen: The mucous membrane in general was pale. The vocal bands were somewhat hyperæmic and thickened, and on phonation failed to approximate. The arytenoids and aryepiglottic folds were normal in appearance. At the posterior commissure, however, in the interarytenoid space there was distinct thickening, the mucous membrane being lobulated and decidedly pale in color. Two wart-like masses could be seen projecting into the lumen of the larynx, no doubt sufficient to interfere with the action of the vocal bands. The ventricular bands were normal, and there was no ulceration present.

The diagnosis of laryngeal tuberculosis was based upon the anæmia of the larynx and the post commissural infiltration. No attempt was made at that time to confirm the diagnosis by microscopic examination of the sputa or of scrapings from the larynx. The subjective symptoms gradually subsided under

treatment, the voice was restored, but the thickening of the posterior wall of the larynx persisted. Several applications of lactic acid were made without any marked effect.

Soon after this, treatment was suspended and the patient disappeared, the correctness of the diagnosis having been seriously questioned, owing to the non-development of pulmonary symptoms, and the steady improvement of the patient's condition.

The patient returned to us in June, 1888, just two years from her first visit. She had improved greatly in appearance, having gained in strength and weight. She said she had been well during the period of her absence. She had married in September, 1887.

I will here remark that the patient had no treatment from June, 1886, to January, 1891, except that at the Manhattan Hospital.

The query quite naturally arises, Was this a case of primary tuberculosis of the larynx, and was this cured by the treatment she received at that time?

When she came for treatment in June, 1888, she was again suffering from cough and hoarseness, but the larynx at this time also did not present the characteristic appearance of the tubercular process, although the thickening and infiltration previously referred to was more marked than on her first visit. There was, however, evidence of beginning pulmonary disease, there being a limited area of dullness at the apex of the left lung.

She attended the clinic with some regularity again for a time, secured relief from the distressing symptoms, and again disappeared.

Since about the 1st of July, 1890, she has failed steadily, though up to that time she had regarded herself as well. This long period of quiescence, covering about three years and a half, is certainly worthy of remark, and attention is called to it in connection with the query already suggested.

The last few months have witnessed the familiar decline, steadily advancing emaciation, increasing cough with expectoration, night sweats, hectic, and loss of strength.

The area of pulmonary involvement has gradually increased, there being at present dullness on percussion down to the sixth intercostal space, upon the left side, with a cavity in the upper lobe.

An examination of the sputa by Dr. Ira Van Gieson, pathologist of the hospital, reveals the presence of tubercle bacilli.

The ulcerative process in the larynx advanced, the larynx presenting for some months past the typical appearance of this disease. There was a steady encroachment upon the lumen of the larynx, due to thickening and infiltration of all the surrounding parts, the interarytenoid thickening being especially noticeable, the latter exaggerated condition being seen by reference to Fig. 1.

This thickening was considered by the members of the staff, who watched the process going on in this larynx, as an inflammatory infiltration rather than an œdema, because of its slow advance, and because of the firmness and solidity of the tissues involved.

For three weeks preceding January 30th last, suffocative attacks came on nightly and increased constantly in severity. There was also marked dyspnoea on exertion. Her general condition declined more rapidly. She had no appetite; was so weak that her visits to the hospital were serious drafts upon her strength. Her expression was one of painful anxiety. It was evident that tracheotomy would soon become necessary because of the steady narrowing of the already dangerously narrow rima glottidis, and that operation was advised by members of the staff.

I resolved to try intubation instead, should it become neces-

\* Read before the Section in Laryngology and Rhinology of the New York Academy of Medicine, October 28, 1891.

sary, and instructed the patient's friends to call upon me in case of emergency. I was called to the case on the evening of January 30, 1891, and found the woman in great distress from the dyspnoea. Respiration, 60; pulse, 126; and temperature, 101.5° F. She was extremely weak, as she had not been able to sleep for several nights. She had been unable to eat, all her energy being expended in the effort to secure sufficient air for existence.

Examination of the larynx revealed a condition which is illustrated in Fig. 1. The vocal bands were more thickened than is shown in the drawing, and, because of the infiltration in the posterior commissure, were fixed in about the position shown, neither separating nor approximating except in slight degree.

The interarytænoid thickening had advanced to such an extent that the vocal cords were covered for fully a third of their length.

The ventricular bands were much thickened and appeared like firm fibrous masses, encroaching upon the rima glottidis upon either side.

The posterior commissural thickening was doubtless responsible most largely for the stenosis, for, besides being an obstruction in itself, it interfered with the movement of the cords.

The drawing represents the condition in inspiration, and the glottis, as shown, is probably slightly larger than the reality. After cocainizing the pharynx and larynx, the attempt was made to insert the largest tube in my case—the O'Dwyer set—that intended for a child of twelve years.

The patient co-operated intelligently and with great coolness, considering her condition.

Three attempts were made to insert this tube, and all the force was employed that it seemed prudent to use, but the tube failed to pass. Even the size smaller met with much resistance—a resistance due largely, no doubt, to muscular spasm.

FIG. 1.

FIG. 2.

The presence of the tube excited violent paroxysms of coughing. After the tube had been in position some minutes, and after the cord attached to it had been removed, the coughing was less severe. Although the tube was so small, the patient breathed much easier than before its insertion, and when I left she was comfortable.

The tube was expelled later during an attack of coughing. The dyspnoea, however, was relieved and the patient passed a better night than for three weeks.

For twenty-four hours following she suffered considerable local pain and swallowed with difficulty, although there had previously been no dysphagia. She also coughed more than usual, expectorating blood-stained mucus, this and the dysphagia being due to the traumatism of intubation.

A reference to Fig. 2, which shows the condition of the larynx five days after intubation, will show why the dyspnoea was relieved, although the tube was worn so short a time.

The force exerted upon the tube tore away a portion of the posterior commissural thickening, and doubtless the remainder subsided somewhat by contraction, and from relief to the engorgement from the bleeding. This allowed the cords an increase of their limited range of motion. Moreover, the removal of that thickening reveals a loss of tissue in the vocal bands before unseen, and which increased slightly the lumen of the larynx.

With the relief of the dyspnoea the patient's appetite again improved, and there followed a gain in strength and general condition.

She resumed her visits to the clinic for a short time on February 17, 1891.

A portion of tissue was removed from the posterior commissural thickening and submitted to Dr. Jonathan Wright for microscopic examination, with the idea that perhaps tubercle bacilli would be found here also. None was observed, but the report is of interest, since it reveals the condition present in the process under consideration.

The following is Dr. Wright's report: "Specimen consists of two or three small masses of tissue about the size of wheat grains. The largest one, when cut and stained, shows the following microscopic structure: the surface is fairly smooth and consists of a layer of pavement epithelium cells, in places of normal thickness, in others considerably proliferated in the 'thorny layer.'

"The basement substance, or body of the mass, is composed of œdematous, fibrous connective tissue, the fibrillæ being separated from one another by infiltrations of serum and fibrin and a few white blood-cells.

"The blood-vessels are some of them enormously dilated and contain granular detritus. There is no glandular structure to be seen. There are no papillæ. The structure is therefore analogous to that of the so-called nasal mucous polypi, excepting that it has, as one would expect in the larynx, an investment of pavement instead of columnar epithelium. Diagnosis: Polypoid degeneration of the mucous membrane of the larynx."

Mrs. B. so far recovered her strength that she not only helps to take care of herself, but assists in the care of her husband, who is now confined to the bed, being in the second stage of pulmonary tuberculosis.

Here, then, is presented another point of interest. Is Mr. B.'s case one of infection?

I will give his history briefly, leaving the question open.

Mr. B., thirty-three years old, born in Maryland of American parentage, is the oldest in a family of three children. A sister died in childhood of diphtheria. A brother is living, aged twenty-nine, and in good health. The mother died at thirty-one of some puerperal disease, two days after the birth of this brother. The father died suddenly, at forty-four, of "heart disease."

Grandparents, paternal and maternal, reached an advanced age.

Of the uncles and aunts, so far as known, but two have died—a paternal uncle, at sixty-three, of consumption, and a paternal aunt, at fifty, cause unknown. Mr. B. is tall and broad-shouldered, and was apparently a man of more than ordinary strength.

He has led a seafaring life since the age of sixteen, and for the latter years was mate of his vessel, a sailing craft. He was married, as already stated, in September, 1887. He was never sick until March, 1888, when he was at sea during the memorable blizzard. He was much exposed at this time, and con-

tracted a severe cold. He has had frequent "colds" since, but has never been confined to the house.

The last attack at sea was after prolonged exposure in August, 1890, when he gave up his position and attempted to find some easier work in the city. Previous to this time his stays at home here had been of a week's duration or less, and at intervals of two or three months.

From August to November, 1890, he drove a mail wagon as a "night extra." He was obliged to give this up at the latter date because of a steady loss of strength.

Since that time he has failed steadily, presenting the familiar symptoms of pulmonary tuberculosis.

The foregoing was written early in March; since then both the patients have died—Mr. B. on April 14th, and Mrs. B. five weeks later. Mrs. B. had no suffocative attacks after the intubation. In fact, during the last weeks of her life the lumen of the larynx, enlarged by the destructive ulceration, was greater than it had been during any time in the preceding year, as shown in Fig. 3.

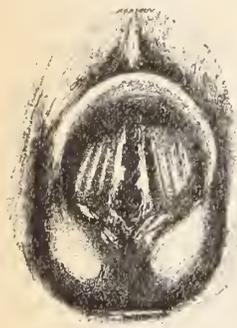

FIG. 3.

The only record of intubation for the relief of stenosis in tubercular laryngitis of which I have been able to learn is that reported in the July number of the *Journal of Laryngology and Rhinology*. M. Massei is reported as having intubated in three cases of tubercular laryngitis. He says of the operation that "stenosis may be got to yield in a surprisingly short space of time."

At the time this paper was written I learned that the operation had twice been done in this city—once by Dr. Dillon Brown; the patient was dying and intubation was done for the promotion of euthanasia; once also by Dr. D. C. Cox, under like circumstances and for the same purpose.

In the condition under consideration it is not unwarrantable to make the assertion that the operation ought always to be done instead of tracheotomy.

The case and quickness with which the operation may be done; the comparative absence of shock; the absence of a wound in tissues predisposed to necrosis; the fact that air reaches the lungs through the natural passages; the possibility that after a few hours or days the tube may be dispensed with—in fact, all the familiar arguments in favor of intubation appeal with great force for its use in these cases.

Instead of tardily and reluctantly yielding to the importunities of friends for relief by tracheotomy—an operation of doubtful utility—one may early offer intubation with as much hopeful enthusiasm as can be summoned in so desperate a condition, knowing that as large a measure of relief will be gained with the doing of relatively no damage.

To put the question simply: Shall the patient be given air by a method which adds materially to his suffering, and rarely prolongs life beyond a narrow limit, or by a method which allows respiration to go on as freely as after tracheotomy, adds nothing to the risks of the sufferer, and offers the possibility of prolonging life to such limit as the general condition allows?

In conclusion, I wish to acknowledge my indebtedness to Dr. Charles H. Knight for his material assistance, and to Dr. Van Gieson and Dr. Wright for their kindness in making microscopic examinations.

## A CONSIDERATION OF FUNCTIONAL DISTURBANCES OF THE HEART AND THEIR REMEDIES,

*with the History of a Case of Functional Trouble  
characterized by Irregular Rhythm and Force  
and Intermittent Action which has persisted for Two Years.\**

By C. E. LOCKWOOD, M. D.

FUNCTIONAL disturbances of the heart, as has been often remarked, comprise the large majority of heart affections for which physicians are consulted, because, as has been noted by Dr. Walshe, "the amount of local suffering entailed by disturbance wholly or in the main dynamic is often greater than that produced by actual organic disease." The importance of their careful study is therefore apparent.

The study of the nervous supply of the heart, upon the derangement of which so many functional irregularities depend, is one surrounded by many difficulties, and our information on this point is very incomplete. It seems to be generally admitted that by the cardiac ganglia at the base of the heart, which are intimately connected with the sympathetic system of nerves, the rhythmical movements are carried on, even when the heart is removed from the body, and that the controlling or inhibitory nerve is the pneumogastric. It is well known, says Dr. Fothergill, that excitation of the pneumogastric will slow ventricular contraction, and, if powerful enough, arrest it altogether. In animals the right possesses the inhibitory power more than the left. In the pneumogastric there are certain fibers which exert an accelerating action and increase the rapidity of the heart's action. Irritation of the medulla oblongata will also produce a similar effect if certain nerve tracts are uninjured; so impaired action of the vagus or stimulation of the accelerating fibers may be the cause of tachycardia. According to Stricker, says Dr. Austin Flint, there exists in the medulla oblongata a center the stimulation of which increases the rapidity of the heart's action, and from this center fibers descend in the substance of the spinal cord, pass out with the communicating branches of the lower cervical and upper dorsal nerves to the sympathetic, and go to the cardiac plexus. It has been shown that, after division of the pneumogastric, stimulation of the accelerator fibers increases the number of beats of the heart. And when we consider how intimately the heart is connected with the brain and other organs, through the pneumogastrics and the sympathetic system, the great wonder is that its functions are not more frequently disturbed. Such derangement of the heart functions as can not be shown during life or after death to be connected with organic lesions we call func-

\* Read before the Section in General Medicine of the New York Academy of Medicine, November 17, 1891.

tional, although some lesion of the organ may exist and not be discoverable by our present methods of examination during life.

Functional disturbance of the heart, according to Walshe, is connected more or less constantly with the following conditions: Perverted innervation, as in hysteria; the menopause; uterine and ovarian excitement; spinal irritation; various neuralgiæ; sudden fright; overexertion of the faculties of the mind; prolonged mental anxiety; chorea; emotion; dyspepsia; gastric catarrh, etc. It is also caused by: *An altered condition of the blood*, due to hæmorrhage, anæmia, gout, chronic rheumatism, functional derangement of the liver, chronic liver disease, or uræmia; *nervous exhaustion*, abuse of the sexual organs, and other causes; *mechanical interference*, as when the stomach or intestines are distended with flatus, and in pregnancy, tight lacing, or pleuritic effusion; and *certain poisonous influences*, such as the use of stimulants, tobacco, etc.

In regard to the actual symptom-producing agent in tobacco, when smoked in excess, there seems to be some difference of opinion among authorities, some contending that nicotine is not present in tobacco smoke. Dr. W. L. Dudley, of Nashville, Tenn., concluded from his investigations that carbonic oxide was the *most poisonous constituent of tobacco smoke*, derived, of course, from combustion; and, further, that more injury resulted from cigarettes than cigars or pipes, as the smoke was *inhaled*, poisoning the blood with carbonic oxide. Nicotine, like prussic acid, is a compound of carbon, nitrogen, and hydrogen; it contains no oxygen, the formula being  $C_{10}H_7N$ . When exposed to air and light it undergoes a chemical change and acquires a brown color; its energy as a poison is thereby reduced. Bernard says he found the *modus operandi* of the partially decomposed poison to be different from that of nicotine. The functions of the lungs and heart were directly affected by it, while the pure poison chiefly spent its physiological action on the capillary circulation. We must therefore conclude that tobacco smoking or chewing to excess is especially disturbing to the heart functions. Dr. Fothergill says: "The effect of tobacco is to render the heart action quicker, beat feebler, and to promote liability to palpitation."

As regards the effects of alcohol upon the heart, it seems to be well settled that in small quantities its first effect is to stimulate the heart, causing a slight increase in frequency and a marked increase in force, accompanying which is a dilatation of the cutaneous capillaries, and probably also those of the brain. In poisonous doses, a lessening of the heart's power by one twentieth and the blood-pressure by one sixth occurs. Nothnagel explains this as a reflex result, due partly to the severe irritation of the vagus, partly to a direct affection of the heart plexus and pneumogastric center in the brain.

Theine and caffeine are powerful neurotic agents, and when indulged in to excess have a very decided action on the cardiac ganglia; according to Dr. Fothergill, they render the heart irritable, excited, and arrhythmical in its contractions. He also says that, "looked at from a chemical point of view, the principles of coffee and cocoa are closely allied

to tea; and it seems difficult to explain how symptoms are relieved by substitution of coffee and cocoa for tea. Still, clinically, the fact remains. It is said tea contains, besides theine, a volatile intoxicating oil, and this may make the difference."

Functional disorders of the heart have been divided into five groups: Slow, intermittent, irregular, and frequent pulse, and inordinate vascular pulsation.

"In the variety characterized by infrequency of the heart's action it may be assumed," says Dr. Flint, "that the causative agency is exerted through the pneumogastriacs. The inhibitory function of this nerve is affected in the same way as by the galvanic current in the experimental observations on animals in illustration of this function." This view is corroborated by the frequent association of this variety of disorder with notable cerebral disturbance. According to Sir Dyce Duckworth, slow pulse has been most frequently noticed after *acute disease*, and has been found in cases of malarial poisoning, after jaundice, or with *increased arterial tension*. *Injuries to the head, meningitis, and cerebral abscess* are also causes of this form of pulse. Dr. Southey, of England, has reported a case where the patient had fibroid thickening of the upper membranes of the spinal cord in which the pulse was quicker than normal. In a paper by Dr. Seymour Taylor, published in the *Lancet*, for June 6, 1891, entitled Remarks on the Slow Heart, the author makes the following observations which he thinks it well to remember:

"1. That there is a series of cases in which it is a perfectly healthy phenomenon, occurring in tall, muscular men, and in whom it is quite consistent with health, and even prolonged life.

"2. That it is often a manifestation of advanced mechanical disease of the heart, or of disease of the aorta and its primary vessels.

"3. That it occurs as a result of prolonged anæmia or other diseased conditions of the blood, including certain fevers.

"4. That it may supervene after abuse of tea, coffee, and tobacco, or the use of various medicinal drugs, as quinine, cocaine, aconite, nitrate of potash, or as the result of some poisons, as from snake-bites.

"5. That it is often a sequel of grave neurotic changes and disorders, and is thus correlated with derangements of respiration, digestion, and other functions.

"6. That we find it also in cases of shock from sudden fright, in epilepsy, and in abdominal injuries or operations."

In regard to the significance of slow pulse as a symptom of organic disease, Dr. Russell, of Birmingham, England, says that he has collected thirty-eight cases of slow pulse, and in thirty of them organic disease was found to coexist; and of three cases in which the pulsations ranged from 26 to 38 a minute, all had been accompanied by organic disease.

Dr. Austin Flint says that cases of slow heart are very rare in healthy subjects, and that a persistent slowness can not be acquired except rarely without some serious impairment of health. This dictum is doubted by Dr. Seymour

Taylor, as he says all departures from normal states tend to increase the frequency of the heart's action.

*Intermittent pulse* is generally caused by dyspepsia, the excessive use of tea, coffee, or tobacco, or gout, sudden fright, etc.

Dr. Webber, of Boston, has published an account of two cases of intermittent pulse following sudden fright in which there were no other symptoms of cardiac disturbance, no murmurs, no enlargement; he regarded them as choreic in character, and the patients both recovered under arsenical treatment.

*Irregular pulse* is due to about the same causes as mentioned under the last head.

*Frequent pulse* is caused by dyspepsia, disease of the liver, or by some deep-seated nervous disorder. The menopause has been assigned as a producing factor of this form of heart disturbance by Professor Kisch, of Prague, who locates the cause in hyperplasia of the ovarian stroma.

*Inordinate vascular pulsation* is found chiefly in middle life and in leucocythæmia. Hysteria and gout are both causes of this form, according to Sir Dyce Duckworth. Dr. Da Costa has described a number of cases in which forced work or slight exertion in those whose constitution had been impaired by poor nutrition or disease seemed to be productive of this trouble; he found it to be most quickly developed in those unaccustomed to fatigue or subject to readily quickened circulation. The symptoms of this form of functional heart disorder have been graphically depicted by Dr. Da Costa, and are great frequency of the action of the heart, constantly recurring attacks of palpitation and pain in the precordial region, an abrupt, jerky impulse, sometimes of irregular rhythm, with a short first sound and a very distinct second sound.

"The disorder is very obstinate, and much exercise is impossible. The malady often exists when the general health is perfect."

Dr. Halbert has recorded two interesting cases of this kind in the *College and Clinical Record*—one in which the pulse was forcible and reached 120 a minute; the other in which the pulse reached 160. In both the impulse was felt over the abdominal and iliac arteries, and auscultation showed no organic disease in either case; treatment by rest in the recumbent posture, restricted diet, and two drops of tincture of aconite every three hours resulted in cure in one case in three weeks; in the other case the same treatment, with the addition of eight grains of quinine three times a day, effected a cure in six days.

The treatment of functional heart disorders would naturally be such as would be indicated by the evident cause when that can be ascertained—in those characterized by perverted innervation, removal of exciting causes, rest, nutrition, tonics, etc.

In hysteria, compound spirit of ether, valerian, and other antispasmodics are useful; at the menopause, the bromides and mild systematic purging, with wet applications to the lower part of the abdomen, combined with suitable dietetic and hygienic measures, as recommended by Professor Kisch.

In cases following or accompanying chorea or caused by sudden fright, arsenic has seemed to be useful.

Where the heart affection is due to dyspepsia, gastric catarrh, anæmia, gout, rheumatism, or disease of the liver or kidneys, the treatment appropriate to such complaints would be indicated.

In nervous exhaustion due to sexual excess, we should remove the cause and use such measures as will restore normal nerve tone.

In mechanical interference with the heart, removal of the cause should be effected, if possible.

Where the trouble is due to the excessive use of alcoholic stimulants, tea, coffee, or tobacco, discontinuance of their use and the administration of heart tonics, such as digitalis, belladonna, and nux vomica, combined with agents which lessen nervous irritation, such as the bromides, are to be used.

As regards the medicinal treatment in general, Dr. Da Costa has found digitalis and digitaline especially useful in cases characterized by inordinate frequency, tincture of aconite in very forcible pulsation, and belladonna and atropine where irregularity was a marked quality.

Dr. Janeway favors the administration of morphine hypodermically for cases of tachycardia, and Sir Walter Foster, of Birmingham, England, recommends quinine in such doses as ten grains, three times daily, with the use of the continuous current applied to the sympathetic in the neck in "run-away pulse." Dr. Solis-Cohen speaks well of sulphate of sparteine in doses of a quarter of a grain, four or five times a day, in cases needing a remedy of comparatively rapid action and regulating power—that is, a power (as he expresses it) to render steady and continuous the previously unsteady and intermittent heart-beats, and recommends belladonna in the irritable, irregular, and feeble overacting heart of some cases of tobacco poisoning.

CASE.—T. C., white, aged twenty-four years, born in Ireland, a collector, consulted me on February 21, 1888.

*Family History.*—His father died at the age of sixty-three years; cause of death, paralysis. His mother died at the age of sixty years; cause of death unknown. He has three brothers and three sisters living and well.

*Personal History.*—He has always been well, except, *he says*, that he had a catarrhal throat affection last fall, and that his stomach has not been in a satisfactory condition for two years. He appears to be of a nervous temperament. He complains that during the past two weeks he has suffered from a soreness over the stomach on moving or walking, has had a headache most of the time, and palpitation occurs on the least exertion; his throat is dry, his bowels are constipated, and he has a burning sensation in the chest.

*Physical Examination.*—The heart's action is irregular in force and rhythm, at times intermittent. The number of pulsations at the wrist is 108, as near as I am able to estimate, the counting of the pulse at the wrist being attended with much difficulty, on account of the difference in the force of the beats, some pulsations being hardly perceptible. The apex-beat is on the mammary line and somewhat raised, and I am unable to detect any murmur. On investigation as to the cause of the troubles, the patient says he thinks his occupation as a collector has been attended with considerable overexertion, as he has been obliged to go up and down many flights of stairs daily. I am unable

to elicit a classical history of dyspepsia. He says he does not smoke or use tobacco in any form, or tea or coffee to excess; neither is there any history of prolonged mental exertion, worry, or sexual excess. He speaks of having been disappointed in love. There are no symptoms of gout. He is somewhat anæmic in appearance, and says he has never had syphilis.

The patient's age (twenty-four years) rather precluded atheroma of the coronary arteries, and his weight (one hundred and twenty pounds and three quarters) and the absence of subcutaneous fat did not indicate fatty degeneration. In view, therefore, of the history of overexertion, mental depression due to disappointment in love, and the evident neurotic temperament of the patient, I diagnosed the case as one of *heart neurosis*, and recommended measures to restore the impaired nerve tone and regulate the action of the heart, with the avoidance of all circumstances calculated to call upon the heart for increased effort, moderate exercise in the open air, no emotional excitement; the drinking of two quarts of milk daily in addition to his usual diet; cod-liver oil with iron after meals; buckthorn cordial, from a teaspoonful to a tablespoonful at bed-time, to overcome constipation; and a mixture of equal parts of tincture of nux vomica and tincture of digitalis, ten drops three times a day.

*September 18, 1888.*—Heart's action the same as when last seen in February, 1888; same treatment advised, except that I prescribed ten drops of tincture of digitalis three times a day.

*September 11, 1889.*—Patient reappears after lapse of one year; heart's action the same; has lost flesh; same general treatment advised; for constipation, aloin, one fifth of a grain; strychnine, one sixtieth of a grain; extract of belladonna, one eighth of a grain at bed-time.

*25th.*—Weight, one hundred and twenty-six pounds, a gain of five pounds since September 11, 1889. Heart's action the same; prescribed one thirty-second of a grain of strychnine and ten drops of tincture of digitalis three times a day to regulate heart action; the application of a belladonna plaster to the chest over the region of the heart, and continuance of general measures as to nutrition and hygiene.

*October 7th.*—Pulse more regular at the wrist; heart action more regular with the exception of some hesitation, so to speak, at times; weight, one hundred and twenty-eight pounds, a gain of seven pounds and a quarter since September 11, 1889; prescribed one twenty-fourth of a grain of strychnine and ten minims of tincture of digitalis three times a day; general treatment continued.

*13th.*—Heart action more regular, but dicrotic every eight beats; prescribed a mixture of strychnine, iron, quinine, and phosphorus, as a general tonic; and for the constipation, which still remained obstinate, maltine with cascara, one or two teaspoonfuls at bed-time.

*December 2d.*—Weight, one hundred and thirty-one pounds, a gain of ten pounds and a half since September. Heart action arrhythmical, hesitating, and dicrotic. Treatment unchanged.

*January 16, 1890.*—Weight, one hundred and thirty-three pounds and a quarter. Heart action the same; prescribed tincture of strophanthus, five drops three times a day.

*February 10th.*—Heart action irregular; prescribed conval-lamarin, one one-hundredth of a grain three times a day.

*March 10th.*—Heart action the same; complains of full feeling in region of the epigastrium, probably due to indigestion; prescribed tincture of nux vomica, eight drops before each meal and five grains of bismuth and soda after eating; and, with a view to regulate heart action, five drops of fluid extract of convallaria three times a day.

*20th.*—Heart intermits every sixth beat, but in other respects

is more regular; prescribed mixture of bismuth, tincture of nux vomica; dilute nitro-hydrochloric acid and pepsin before meals to aid digestion.

*April 1st.*—Weight, one hundred and thirty-three pounds. Heart intermits about every tenth or fifteenth beat, but more regular in other respects, due perhaps to better action of the stomach.

*11th.*—Heart action dicrotic every tenth beat; prescribed tincture of digitalis and tincture of strophanthus, equal parts, ten drops three times a day.

*May 7th.*—Heart action irregular as to rhythm; prescribed sulphate of sparteine, one fourth of a grain three times a day.

*June 3d.*—Heart action more regular; intermissions occur every twenty beats; advised to keep up nutrition and continue cod-liver oil.

*October 14th.*—Weight, one hundred and twenty-three pounds; loss in weight since May, 1890, ten pounds. Heart intermits every ten or fifteen beats; prescribed cod-liver oil, iron, and two quarts of milk in addition to regular meals.

*30th.*—Weight, one hundred and twenty-seven pounds and five eighths. Pulse, 84; no intermission, but occasionally notice a double beat; prescribed tincture of digitalis, ten minims, and one thirty-second of a grain of strychnine three times a day.

*December 15th.*—Dr. R. C. M. Page, at my request, made a careful examination of the patient with the following result: Liver and spleen normal; apex beat of the heart on the mammary line and somewhat raised; intermission felt best in the carotids; eyesight good; no enlargement of the thyroid gland; respiratory murmur perfect, except it is wavy, which is peculiar to nervous people with palpitation; false intermission at the wrist; anæmic murmur in the pulmonary interspace; venous hum marked in the neck at the right side.

Dr. Page expressed the opinion that the case was a heart neurosis with anæmia, and well worth watching for the development of exophthalmic goitre. Prescribed a mixture of tincture of nux vomica, two drachms; powdered rhubarb and sodium bicarbonate, each one drachm; water, to two ounces. A teaspoonful to be taken before meals and at bedtime.

Dr. Page thought that gastric catarrh, torpid liver, or anæmia might produce such a neurosis. Urine examined: reaction acid; specific gravity, 1.020; no sugar; no albumin; some crystals of oxalate of calcium and some urates found.

*February 9, 1891.*—Heart action the same. Patient was carefully examined by Dr. Janeway, who found the heart slightly enlarged with displacement of the apex to mammary line and raised; found no adhesions between visceral and parietal layers of the pericardium; slight murmurs were heard at the apex, which he thought due to irregular action of the papillary muscles. Dr. Janeway thought the hypertrophy was due to the irritable heart condition and said the murmurs were more audible after rapid exercise or partial respiration, and expressed the opinion that the trouble was a heart neurosis choreic in character, and advised that the patient take a mixture of equal parts of tincture of strophanthus and tincture of nux vomica, ten drops three times a day; that he pay careful attention to his general health and avoid all excitement; and for stomach symptoms, a mixture of tincture of nux vomica, bicarbonate of sodium, and rhubarb, and three grains of salicin three times a day.

*March 3d.*—Pulse, 84; heart action the same. In view of the choreic nature of the case, I prescribed Fowler's solution of arsenic, two drops to be taken after meals, and the dose to be gradually increased up to ten drops.

*May 13th.*—Patient has taken Fowler's solution of arsenic in gradually increasing doses until he reached ten drops three times a day. Heart action unchanged. Prescribed one sixtieth of a grain of atropine, to be taken three times a day, in accord-

ance with Dr. Da Costa's view that this drug is especially useful in irregular action of the heart.

25th.—Heart action still irregular in force and rhythm.

The points of interest in this case seem to me to be—

1. The evident neurotic character of the affection, its persistency, and the very slight annoyance or discomfort experienced by the patient.

2. The difficulty of assigning a cause for the irregular heart action.

3. The inefficacy of all medication looking toward regulation of the disturbed heart action.

*Guy's Hospital Reports*, London, 1858. On Poisoning by Nicotina, with Remarks. By A. S. Taylor.

**A Bill to restrict the Use of Hypnotism**, drafted, it is said, in the office of the *Buffalo Enquirer*, has been introduced into the New York Legislature. The bill is as follows:

*An act to prohibit public exhibition of hypnotic experiments and to prohibit hypnotic treatment by any one except duly licensed physicians.*

The people of the State of New York represented in Senate and Assembly do enact as follows:

Section 1. It shall be unlawful for any person except duly licensed physicians in the course of lectures to medical students or before scientific bodies to give exhibitions of or perform hypnotic demonstrations in public.

Section 2. It shall be unlawful for any person not a duly licensed physician to hypnotize another.

Section 3. Any person violating either of the foregoing provisions of this act shall be guilty of a misdemeanor.

Section 4. This act shall take effect immediately.

The bill is warmly advocated by several Buffalo physicians, and will doubtless have the support of the medical profession throughout the State.

FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, FEBRUARY 27, 1892.

#### THE BABY STUDENTS' RELIEF BILL.

In our issue for February 13th we spoke of the disgraceful purport of a bill that was then under consideration by a committee of the Senate of the State of New York, having for its object to relieve certain medical students of the necessity of passing the State examination. We are glad to see that the committee on legislation of the Medical Society of the State of New York has since issued a circular, dated February 17th, calling on the physicians of the State to influence members of the Assembly to vote against the bill, which has already been passed in the Senate. The committee very properly says in its circular that there is no valid argument in favor of the bill, but that its passage by the Senate has been brought about by personal solicitation and selfish appeals. Personal effort should therefore be resorted to against it in the Assembly.

"The law governing the practice of medicine in the State of New York," says the circular, "is being copied all over the country; it is said by educators to be one of the fairest and best laws on the statute books of any government in the world; almost daily requests for a copy of this law are received from all quarters of the globe, and its praises have been sounded in congratulatory letters to its projectors by physicians and laymen from far and near. Should such an excellent law, passed after more than twenty years of struggle in legislative halls, be emasculated year after year because of the lethargy of our professional brethren, when those selfishly interested are so energetic and persistent? The answer rests with you and all of us. If you desire to crush out this yearly cry on the part of the students against high medical standards, if you desire to preserve intact the excellent law which it is now sought to amend and practically nullify, write or telegraph your member of Assembly *at once* (delay is now dangerous) that the entire medical profession, not only of the State but of the country, regardless of creed or pathy, is opposed to Assembly Bill No. 513; that it is special and selfish legislation calculated to benefit the few to the detriment of the many, *and that it should not prevail*. If you value a higher standard in the profession of medicine, if you believe in adding to its dignity and worth, you will not put this letter aside until you have lent your aid toward the defeat of this proposed legislation."

Besides issuing its circular, the committee has worked diligently by individual correspondence to rouse the profession to the need of speedy action, and we are informed that a most gratifying response has been the result. The medical societies of Fulton, Albany, Kings, Erie, and other counties had delegations present at a hearing held on Wednesday, the 24th inst., before the Assembly committee on public health, and there

were also present representative physicians from New York city, Brooklyn, Buffalo, Elmira, Syracuse, Gloversville, Albany, and other large places—homœopathic and eclectic as well as those of our own “school”—to protest against the proposed legislation. In addition, several of the more influential of the newspapers have published editorial articles opposing the bill.

It must not be supposed that all the students who could take advantage of the proposed law are enlisted in favor of its enactment; indeed, in one school, that of Niagara University, of Buffalo, they have passed a resolution declaring that the law as it stands is good enough for them.

The Legislature should understand that the medical profession opposes the bill not from any selfish or illiberal motives, but solely in the interest of the public welfare; all that the profession asks for itself is not to be deprived of the means of keeping itself clean.

MINOR PARAGRAPHS.

AN ASYLUM FOR SUPERANNATED INSTRUMENTS.

ACCORDING to a London letter to the *American Practitioner and News* for January 16th, old and discarded surgical instruments can be put to a good purpose by being sent to missionaries in foreign lands. A benevolent member of the Royal College of Surgeons has made a suggestion that all old-fashioned and discarded surgical implements be brought out of their dark corners and placed in the hands of the secretaries of those societies which employ medical missionaries. The gentleman who makes this appeal states that he knows of an instance of a missionary who had no other instruments than an ordinary case-knife and a pair of scissors with which to remove the frozen foot of a North American Indian in whose case an operation was so imperative that he proceeded to operate with these. Fortunately the patient survived. A beginning has already been made by forwarding certain superfluous instruments and appliances to the Missionary Training College in East London. Old operating-cases, dental instruments, tourniquets, trocars, sounds, catheters, etc., may all be welcome and find their best value in the hands of those lonely pioneers, many of whom are a hundred miles distant, perhaps more, from any possible assistance.

COMPRESSION OF THE CAROTIDS AS A THERAPEUTIC MEASURE.

IN a recent number of the *Gyógyászat* Dr. Leopold Roheim, of Budapest, publishes a case of eclampsia which he had, after the failure of a large number of remedies, successfully treated by compressing the carotids with his fingers. The publication of this case recalls the fact that the whole subject of carotid compression in its relation to the treatment of nervous diseases was thoroughly worked up by Dr. J. Leonard Corning over ten years ago. Not content with following the ancient practice of pressing upon the carotids with the fingers, Dr. Corning devised a number of ingenious instruments by means of which he was able to compress those arteries and faradize the subjacent sympathetic and pneumogastric nerves at the same time. He has embodied the results of these researches in a number of papers, and notably in a little book, *Carotid Compression*, published in 1882. Dr. Corning's contributions are especially valuable, as the conclusions arrived at are based upon a large array of cases of nervous disease in which the method was given a thorough trial. Cases of headache, eclampsia, convulsions of children,

epileptic convulsions, and obstinate insomnia as it occurs in the insane were treated successfully in this way.

MONTHLY BULLETIN OF THE SECRETARY OF THE RHODE ISLAND STATE BOARD OF HEALTH.

DR. CHARLES H. FISHER, of Providence, has begun again to publish his little sanitary serial, called the *Bulletin of the State Board of Health*. It was discontinued in June, 1891. The fourth volume opened in January, 1892. It is essentially a voluntary publication on the part of Dr. Fisher, whose purpose is the double one of having a printed record of mortality, meteorology, etc., for the use of health officials and for enlightening the public and the public schools about the sanitary duties of boys, girls, teachers, and citizens. The Rhode Island Institute of Instructors has found this latter feature so well carried out that it has publicly asked Dr. Fisher to continue the publication and has promised a liberal advocacy of its objects.

HIGH TEMPERATURE IN INTERMITTENT FEVER.

DR. STEPHEN MACKENZIE, in the *British Medical Journal* for February 13th, reports a case of intermittent fever in which twice the temperature was 107° F., once 109°, twice 113°, and once 113·8°. The observations were made with the thermometer in one or the other axilla; sometimes two thermometers were placed in the axilla and found to correspond. On account of rigors the temperature could not be taken in the mouth. The periods of hyperpyrexia were exceedingly brief, sometimes a return to normal temperature occurring in five minutes. The patient recovered.

A BENGALI MEDICAL JOURNAL.

THE *Indian Medical Gazette*, of Calcutta, says in its January number that it has received the first and second issues of *Veshukdorpon* (the mirror of medicine), a monthly medical journal written in simple Bengali, so that it can be read by the native doctors and civil hospital assistants of all grades and denominations. The character of its contents is commended by the *Gazette*.

ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending February 23, 1892:

DISEASES.	Week ending Feb. 16.		Week ending Feb. 23.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus.....	86	0	16	4
Typhoid fever.....	7	6	13	5
Scarlet fever.....	225	39	209	31
Cerebro-spinal meningitis.....	0	1	0	1
Measles.....	204	10	224	17
Diphtheria.....	123	37	134	35
Small-pox.....	8	1	7	3
Erysipelas.....	4	0	2	0
Varicella.....	18	0	16	0
Pertussis.....	1	3	2	0
Mumps.....	0	0	4	0

**The County Society Prize.**—Members of the Medical Society of the County of New York are invited to compete for the annual prize of one hundred dollars or a one-hundred-dollar gold medal, to be awarded for the best essay on any medical or surgical subject by the society at its annual October meeting, the award being subject to the following conditions:

1. The competitor must be a member of this county society in good and regular standing.

2. The competitor's identity must not be revealed until after the report of the committee on prize essays has been presented at the annual October meeting, each essay in competition being designated simply by a motto and accompanied by a sealed envelope exhibiting the same motto, and inclosing the author's name.

3. If, in the judgment of the committee, no essay is presented that is sufficiently meritorious, no award will be made.

All essays competing should be sent to the chairman of the committee, Dr. E. B. Bronson, No. 123 West Thirty-fourth Street, on or before the first day of October, 1892.

**The Medical Association of Georgia** will hold its forty-third annual meeting in Columbus, on April 20th, 21st, and 22d, under the presidency of Dr. G. W. Mulligan, of Washington.

**The Randall's Island Hospitals.**—Dr. William J. Morton has been appointed neurologist on the medical board.

**The Pan-American Medical Congress.**—The Medical Society of the County of Kings, N. Y., has appointed a committee consisting of Dr. J. H. Raymond (chairman), Dr. A. J. C. Skene, and Dr. Alexander Hutchins to co-operate with the officers of the congress.

**The Royal College of Physicians of London.**—It is stated that the recently published list includes 295 fellows, about 500 members, and about 3,300 licentiates. Only the fellows manage the organization.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 7 to February 20, 1892:*

GLENNAN, JAMES D., First Lieutenant and Assistant Surgeon. The leave of absence granted on surgeon's certificate of disability is extended fifteen days.

FISHER, WALTER W. R., Captain and Assistant Surgeon. The leave of absence granted is extended fifteen days.

The following named officers, having been found by army retiring boards incapacitated for active service on account of disability incident to the service, are, by direction of the President, retired from active service this date, under the provision of Section 1251, Revised Statutes: BURTON, HENRY G., Captain and Assistant Surgeon; TAYLOR, ARTHUR W., Captain and Assistant Surgeon. February 5, 1892.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the week ending February 13, 1892:*

BRYANT, P. H., Assistant Surgeon. Ordered to the Naval Hospital, Philadelphia, Pa.

PERCY, H. T., Passed Assistant Surgeon. Detached from Coast Survey Steamer Patterson and granted leave for two months.

DECKER, C. J., Passed Assistant Surgeon. Detached from Naval Hospital, Philadelphia, and ordered to Coast Survey Steamer Patterson.

URIC, JOHN F., Passed Assistant Surgeon. Ordered to the Naval Hospital, Portsmouth, N. H.

WELLS, HOWARD, Surgeon. Detached from the Naval Hospital, Portsmouth, and to wait orders.

GUTHRIE, JOSEPH A., Assistant Surgeon. Ordered to Naval Station, Port Royal, S. C.

YOUNG, L. L., Assistant Surgeon. Detached from Naval Station, Port Royal, S. C., and ordered to the Receiving-ship Independence.

**Marine-Hospital Service.**—*Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the three weeks ending February 6, 1892:*

PURVIANCE, GEORGE, Surgeon. Detailed as chairman of the Board of Examiners. February 3, 1892.

HUTTON, W. H. H., Surgeon. Detailed as member of the Board of Examiners. February 3, 1892.

SAWTELLE, H. W., Surgeon. Granted leave of absence for ten days. January 30, 1892.

IRWIN, FAIRFAX, Surgeon. Granted leave of absence for fourteen days. January 26, 1892.

MEAD, F. W., Surgeon. Detailed as recorder of the Board of Examiners. February 3, 1892.

CARTER, H. R., Passed Assistant Surgeon. Granted leave of absence for seven days. January 20, 1892.

CARMICHAEL, D. A., Passed Assistant Surgeon. When relieved, to proceed to Port Townsend, Washington, and assume command of the service. January 23, 1892.

GLENNAN, A. H., Passed Assistant Surgeon. When relieved, to proceed to South Atlantic Quarantine and assume command of the station. January 23, 1892.

WHITE, J. H., Passed Assistant Surgeon. Relieved from duty at South Atlantic Quarantine; to assume command of the service at Savannah, Ga. January 20, 1892.

CARRINGTON, P. M., Passed Assistant Surgeon. When relieved, to proceed to Evansville, Md., and assume command of the service. January 20, 1892.

MAGRUDER, G. M., Passed Assistant Surgeon. Relieved from duty at New Orleans, La.; to assume command of the service at Portland, Oregon. January 23, 1892.

VAUGHAN, G. T., Assistant Surgeon. When relieved, to report to the Supervising Surgeon-General. January 20, 1892.

COBB, J. O., Assistant Surgeon. Ordered to examination for promotion. February 3, 1892.

STONER, J. B., Assistant Surgeon. Ordered to examination for promotion. February 3, 1892.

CONDUCT, A. W., Assistant Surgeon. When relieved, to proceed to Wilmington, N. C., and assume command of the service. January 23, 1892. Ordered to examination for promotion. February 3, 1892.

GARDNER, C. H., Assistant Surgeon. Assigned to temporary duty at Baltimore, Md. January 27, 1892.

#### Promotions.

CARTER, H. R., Surgeon. Commissioned by the President as Surgeon. January 28, 1892.

VAUGHAN, G. T., Passed Assistant Surgeon. Commissioned by the President as Passed Assistant Surgeon. February 6, 1892.

#### Appointment.

GARDNER, C. H., of Maryland. Commissioned by the President as Assistant Surgeon. January 28, 1892.

#### Society Meetings for the Coming Week:

MONDAY, *February 29th*: Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

TUESDAY, *March 1st*: New York Obstetrical Society (private); New York Neurological Society; Elmira Academy of Medicine; Buffalo Medical and Surgical Association; Ogdensburgh Medical Association; Hudson, N. J., County Medical Society (Jersey City); Androscoggin, Me., County Medical Association (Lewiston); Essex, Mass., South District Medical Society (annual—Salem); Baltimore Academy of Medicine.

WEDNESDAY, *March 2d*: Society of the Alumni of Bellevue Hospital; Harlem Medical Association of the City of New York; Medical Microscopical Society of Brooklyn; Medical Society of the County of Richmond (Stapleton); Penobscot, Me., County Medical Society (Bangor); Bridgeport, Conn., Medical Association.

THURSDAY, *March 3d*: New York Academy of Medicine; Brooklyn Surgical Society; Society of Physicians of the Village of Canandaigua; Boston Medico-psychological Association; Obstetrical Society of Philadelphia; United States Naval Medical Society (Washington).

FRIDAY, *March 4th*: Practitioners' Society of New York (private); Baltimore Clinical Society.

SATURDAY, *March 5th*: Clinical Society of the New York Post-graduate Medical School and Hospital; Manhattan Medical and Surgical Society (private); Miller's River, Mass., Medical Society.

#### Answers to Correspondents:

No. 372.—You do not state what form of electricity you have used. We should expect a favorable action from local faradization, using a weak current; also from the administration of drop doses of tincture of cantharides hourly for four hours each day.

No. 373.—We think not.

## Book Notices.

*Therapeutics: its Principles and Practice.* By H. C. Wood, M. D., LL. D., Professor of Materia Medica and Therapeutics, and Clinical Professor of Diseases of the Nervous System, in the University of Pennsylvania. A work on Medical Agencies, Drugs, and Poisons, with special reference to the Relations between Physiology and Clinical Medicine. Eighth edition of A Treatise on Therapeutics, rearranged, rewritten, and enlarged. Philadelphia: J. B. Lippincott Co., 1891.

This oft-reviewed work comes to us in its eighth edition, enlarged and improved, but not revolutionized as in its seventh edition. Its favorable reception and flattering reviews, if indeed any praise could flatter it, by the profession of not only our own, but almost every civilized country, leave little to be said for it which would not be trite and commonplace. In the branch of therapeutics, however, so many discoveries and so much experimentation are being made that a book which was authority three years ago would be at best a book of reference to-day. The author must be wide awake and ever on the alert to study new drugs, new works and conclusions upon old ones, and new theories and methods of applying them. In this respect, as in others, Dr. Wood has proved himself a man of diligence and careful scrutiny.

No doubt there are many of the newer remedies that he has failed to notice in his work, but most of them are very new or have not as yet established their right to a place among the standard therapeutic agencies. One of the greatest charms in the study of this work is that the reader is not asked to believe upon general hearsay. The studies have been made by the author himself, or his conclusions drawn from competent authorities, which he invariably cites. The facts of experimentation are presented and the author's conclusions therefrom laid down, leaving the reader the liberty to draw different ones if the processes of reasoning seem imperfect to him. It is not a work of dogmatic axioms, but one of rationalism in therapeutics, and it directs the practitioner to a higher plane than that of the older works, which, teaching from empiricism, told the student that mercury was good for syphilis, quinine for fever, and opium for diarrhœa. It would be impossible in our space to point out the different features worthy of commendation in this work; the points for criticism are few and far between. The most serious fault we can find with the book is the meagerness of advice with regard to the application of remedies in special diseases. If every reader was a practical physiologist or thorough logician, this would not be a fault; but such is not the case, and a fuller list under each drug of the diseases in which it has been successfully used would make the work more popular at least.

The arrangement of the drugs in classes, according to their physiological actions, is to our mind the only scientific and satisfactory one, both for reference and for study. The division of the work into two parts will be a novelty to most of Dr. Wood's older students. Part I, on Remedies, Remedial Measures, and Remedial Methods which are not Drugs, comprises a new and interesting portion of the book. Here are treated not only the general considerations and miscellaneous remedial measures—such as massage, metalotherapy, and feeding of the sick—but also the management of general bodily conditions, including exhaustion, obesity, and the gouty diathesis. Divisions are also made of Heat and Cold and Electricity, all of which are treated of in the author's clear and convincing manner. On the whole, this is a work worthy of the high place it has taken in medical literature and one of which every American should be proud.

*Lessons in the Diagnosis and Treatment of Eye Diseases.* By CASEY A. WOOD, C. M., M. D., formerly Clinical Assistant, Royal London Ophthalmic Hospital (Moorfields), etc. With numerous Woodcuts. Detroit: George S. Davis, 1891.

This little manual is intended to aid the physician to detect and treat the diseases of the eye which are most frequently overlooked in the course of general practice. It is subject to the same criticism which may be made regarding most of the manuals of this series, that too much is attempted to be told in a small space.

*The Pathology, Diagnosis, and Treatment of Intracranial Growths.* By PHILIP COOMBS KNAPP, A. M., M. D. (Harvard), Clinical Instructor in Diseases of the Nervous System, Harvard Medical School, etc. Boston: Rockwell & Churchill, 1891.

This is the essay for which was awarded the Fiske prize for 1890. Dr. Knapp wisely decided to present a series of new cases, even though some of them were defective, rather than to collect more typical published cases from the great number already reported. The essay is therefore based on the records of forty personal cases with autopsies. He has, however, availed himself freely of the literature of the subject, especially in the discussion of symptomatology. In the chapter on treatment also he has given a complete list of all reported cases of operations.

Of the forty cases collected by the author, eleven were not uncomplicated cases of brain tumor, but cases in which the patient died of something else, and the tumor was merely a co-existing lesion, giving rise during life to no apparent disturbance.

In thirteen cases there were symptoms of some cerebral trouble, but they were not definite enough to permit of a correct diagnosis. In only sixteen cases was it possible to make a diagnosis of the existence of an intracranial growth, and in eight of these a correct focal diagnosis was also made. The number of characteristic cases, when thus analyzed, is so small that the author could hardly do more than use them in illustration of facts already established, rather than attempt to add to our existing knowledge of the subject. He gives, however, a very clear and complete exposition of this knowledge, especially in the chapters on symptomatology and diagnosis. His remarks on treatment also are characterized by a judicious conservatism.

*Philadelphia Hospital Reports.* Vol. I, 1890. Edited by CHARLES K. MILLS, M. D., Member of the Neurological Staff. Philadelphia: Detre & Blackburn. 1891.

This publication should receive a warm welcome from the medical profession in this country. Those physicians who are familiar with the reports published by Guy's Hospital and other institutions abroad have long regretted the regular publication of similar works in the United States.

A part of this volume is given up to historical sketches and reminiscences of the Philadelphia Hospital and Almshouse, beginning with their establishment early in the last century. The almshouse was founded in 1742, and the hospital proper in 1753, and it is but fitting that their ancient origin should receive recognition in this initial volume.

The main body of the work is made up of twenty-five clinical reports by various members of the medical staff. Neurology is represented by Dr. Mills, Dr. Dercum, and Dr. Sinkler; surgery, by Dr. Porter and Dr. Deaver; general medicine, by Dr. Musser, Dr. Henry, and Dr. Solis-Cohen; obstetrics, by Dr. Hirst and Dr. Davis; and pathology, by Dr. Forward. An interesting experimental study of the *Bacillus subtilis*, by Dr. J.

Leffingwell Hatch, should also be mentioned. His conclusions are in agreement with the opinion of Klein that this bacillus represents a class of non-pathogenic bacilli.

There are other writers whose names are only less well known than those given above, almost every member of the large hospital staff having contributed one or more papers.

Philadelphia is to be congratulated on this evidence of medical enterprise, and we hope that New York will not be tardy in following her good example.

*Guy's Hospital Reports.* Edited by W. DAVIES-COLLEY, M. A., M. C., and W. HALE WHITE, M. D. Vol. XLVII, being Vol. XXXII of the Third Series. London: J. & A. Churchill, 1890.

This volume, in addition to the usual number of valuable clinical studies, contains a very interesting and discriminating memoir of the late Sir William Gull. An autotype portrait completes the impression gathered from the memoir, and gives one a good idea of the striking presence of that distinguished physician.

As to the reports themselves, it is difficult to single out any for special mention. There are two, however, that we have found unusually instructive—namely, a paper entitled Chiefly concerning Bruits, by Dr. GOODHART, and another by Dr. W. Hale White, on The Pathology and Prognosis of Pernicious Anæmia.

Dr. C. H. Golding-Bird also contributes an interesting study of Congenital Wryneck and Facial Hemiatrophy, in which he advances a new and striking theory of the pathology of these affections when associated in the same individual.

Other reports by various writers combine to make a volume full of clinical information.

*On the Medical and Surgical Uses of Electricity.* By GEORGE M. BEARD, A. M., M. D., and A. D. ROCKWELL, A. M., M. D., etc. Eighth Edition, with over 200 Illustrations. New York: William Wood & Co., 1891.

To this edition the surviving author, Dr. Rockwell, brings broadened views and a richer experience. The vagueness and uncertainty that formerly occupied some of its pages have in a large measure been eliminated, and in place of suggestions we have experiences and positive advice. The chapter upon dosage in electricity is well-worded and instructive, being a great improvement upon that in the former editions. The chapter upon the different physiological and therapeutic effects of the induced current is new and highly interesting. The cuts, many of them new, are not of the highest type, but are generally accurate. In attempting to show the application of electricity to every form of disease much useless material has been brought into the book, and this, too, without giving the negative conclusions which the experiences justify. We do not depreciate the usefulness of electricity in many conditions, but it is not well to allege for it curative virtues in every ill that flesh is heir to. Dr. Rockwell would inspire more confidence if he told us candidly that there were some infirmities in which electricity was of no use. Fewer cases with more detail would give the student a better idea of the methods of applying electricity and of its ultimate results. On the whole, this work deserves its popularity.

#### BOOKS, ETC., RECEIVED.

*A Manual of Operative Surgery.* By Frederick Treves, F. R. C. S., Surgeon to and Lecturer on Anatomy at the London Hospital, etc. With Four Hundred and Twenty-two Illustrations. Vol. I.: General

Principles; Anaesthetics; Operations upon Arteries and Nerves; Amputations; Excisions; Operations upon Bones, Joints, and Tendons. Pp. xvi to 775. Vol. II.: Plastic Surgery; Operations upon the Neck and Abdomen; Operations upon Hernia; Operations upon the Bladder, Scrotum, Penis, and Rectum; Operations upon the Head and Spine, Thorax, and Breast. Pp. xiii to 775. Philadelphia: Lea Brothers & Co., 1892. [Price, \$9.]

*A Dictionary of Treatment; or, Therapeutic Index, including Medical and Surgical Therapeutics.* By William Whitla, M. D., Professor of Materia Medica and Therapeutics in the Queen's College, Belfast, etc. Revised and adapted to the Pharmacopœia of the United States. Philadelphia: Lea Brothers & Co., 1892. Pp. 9 to 921. [Price, \$4.]

*Surgical Diseases of the Ovaries and Fallopian Tubes, including Pregnancy.* By J. Bland Sutton, F. R. C. S., Assistant Surgeon to the Middlesex Hospital, etc. With One Hundred and Nineteen Engravings and Five Colored Plates. Philadelphia: Lea Brothers & Co., 1892. Pp. xvi to 500.

*First Lines in Midwifery: a Guide to Attendance on Natural Labor for Medical Students and Midwives.* By G. Ernest Herman, M. B. Lond., F. R. C. P., Obstetric Physician to the London Hospital and Lecturer on Midwifery, etc. With Eighty Illustrations. Philadelphia: Lea Brothers & Co., 1892. [Price, \$1.25.]

*The New Cure of Consumption by its own Virus. Illustrated by Numerous Cases.* By J. Compton Burnett, M. D. Second Edition, revised and enlarged. Philadelphia: Boericke & Tafel, 1892. Pp. xi-13 to 187.

*Sleep, Insomnia, and Hypnotics.* By E. P. Hurd, M. D., Member of the Massachusetts Medical Society, etc. Detroit: George S. Davis, 1891. [The Physicians' Leisure Library.]

*Notes on General versus Local Treatment of Catarrhal Inflammations of the Upper Air-tract.* By Beverley Robinson, M. D., New York. [Reprinted from the *Climatologist*.]

*Apparatus for collecting Water for Bacteriological Examination.* By Samuel G. Dixon, M. D., Philadelphia. [Reprinted from the *Times and Register*.]

*Annual Address before the State Board of Health of Pennsylvania.* By Professor Samuel G. Dixon, M. D. (Read on May 15, 1891, at the Sanitary Convention at Altoona.)

*Injury to the Spine: Invention and Application of Paper Jacket.* By J. Marshall Hawkes, M. D., New York. [Reprinted from the *Medical News*.]

*The Part played by Leucocytes in Inflammation in the Light of Recent Bacteriological Investigations.* By William T. Howard, Jr., M. D., Baltimore. [Reprinted from the *Maryland Medical Journal*.]

*Pneumonic Fever; its Mortality, with a Consideration of some of the Elements of Prognosis.* By Edward F. Wells, M. D., Chicago. [Reprinted from the *Journal of the American Medical Association*.]

Twenty-first Annual Report of St. Catherine's Hospital, Brooklyn.

## Reports on the Progress of Medicine.

### REPORT ON OPHTHALMOLOGY.

By CHARLES STEDMAN BULL, M. D.

(Continued from page 222.)

**Clinical Contributions to the Physiology of the Ophthalmic Ganglion.**—Querenghi (*Arch. d'ophthal.*, xi, 3) draws the following conclusions from his observations: 1. Through the ophthalmic ganglion pass the nervous fibers by means of which the irritation or impulse is conveyed to the muscle of accommodation. 2. The ganglion is also traversed by the constrictor nervous fibers going to the pupil, which react to reflex irritation of the same eye. 3. It presides over the particular sensibility of the cornea. 4. The constrictor nerve fibers of the pupil, which react to the luminous reflex of the other eye and to the movements of convergence, come directly from the central organs with

out the intermediary aid of the ganglion. These fibers probably pass to the eye with the long ciliary nerves.

**The Origin of Tuberculosis of the Uveal Tract.**—Valude (*Arch. d'ophthal.*, xi, 3) gives the results of his experiments as follows: 1. As long as the tuberculous deposit remains inclosed with the envelopes of the eye, and as long as no tuberculous fungi develop, the disease extends but little beyond its original deposit. 2. In an infected organism the wounding of the healthy eye is not followed by any special reaction. It thus seems that the eye behaves toward the tuberculous infection very differently from the way the subcutaneous cellular tissue or the bones or articulations behave. 3. The propagation of the tuberculous germs follows by the lymphatic channels, and not by the blood-vessels. 4. The eye is well protected against tuberculosis by propagation or generalization; ocular tuberculosis of internal origin is certainly very rare. 5. It is therefore probable that ocular tuberculosis of the uveal tract is of external origin.

**Superficial Ciliary Nerves in Man.**—Boucheron (*Arch. d'ophthal.*, xi, 4) considers that our modern methods of microscopical examination have proved that it is possible to divide and resect the deep ciliary nerves without destroying the cornea, because the superficial ciliary nerves suffice to preserve its normal sensibility. After division of the deep ciliary nerves the corneal sensibility, preserved at the margin, is merely the normal condition of function of the superficial ciliary nerves. The observations of Magendie and Bernard have also demonstrated that the sensibility of the center of the cornea is of different origin from the sensibility of the periphery of the cornea and conjunctiva.

**Recent Researches into the Physiology of the Movements of the Eyes.**—Landolt (*Arch. d'ophthal.*, xi, 5) draws the following conclusions from his researches: It is proved that the act of reading is the more fatiguing the smaller the jerks or excursions of the eyes are which it demands. Experiments as to the smallest angle of excursion rapidly cause such fatigue that they can not be pursued for any length of time without a rest. The nearer the eye approaches the type, the greater become the necessary excursions of the eyes, and this imposes a great demand on the muscles of convergence and accommodation. The particular kind of motility of the eyes, and the limitation of their excursions, probably contain the solution of many of the problems of ocular pathology.

**Persistence of the Canal of Cloquet; Remains of the Fœtal Hyaloid System; Coloboma of the Optic Nerve.**—Van Duyse (*Arch. d'ophthal.*, xi, 5) gives the following results of his examination of an interesting case: 1. The canal of Cloquet with the remains of the hyaloid artery become impermeable to the passage of the blood. 2. A long, white band of tendinous aspect covers the optic disc with its superior end, and masks the origin of the retinal vessels. It runs downward and outward toward the periphery of the fundus, and ends here by a bilobed border with pigmented edge. The lower end resembles strongly a coloboma of the fundus. 3. There was a coloboma of the sheath of the optic nerve, which surrounded like a large conus the upper end of the tendinous band. There were also signs of disseminate chorioretinitis in the atrophic stage.

**The Shape of the Human Cornea, and its Influence on the Vision.**—Sulzer (*Arch. d'ophthal.*, xi, 5) gives the following results of his investigations:

1. The central parts of the cornea vary very little from the shape of a spherical cap or coil.

2. At a certain distance from the point of intersection of the visual line with the cornea, averaging an angular distance of  $15^\circ$ , the radius of curvature of the cornea suddenly begins to increase. From this point the corneal surface presents curvatures resembling those of an ellipsoid, the eccentricities of which increase as the corneal limbus is approached.

3. If we pass from the point of intersection of the visual line with the cornea, or from the point of greatest curvature, toward the corneal elements situated at equal distances from the point of departure, the curvature does not diminish equally along the two principal meridians nor along the two halves of the same principal meridian.

**Subconjunctival Injections of Corrosive Sublimate in Ocular Therapeutics.**—Darier (*Arch. d'ophthal.*, xi, 5) considers this method of treatment a valuable acquisition of ocular therapeutics. In all cases

where mercurial medication is indicated, and where it is necessary to put an immediate stop to the progress of the disease, he thinks no other method is so easily managed or so satisfactory in its results.

**Notes on Glioma Retinæ, with a Report of Sixty Cases.**—Lawford and Collius (*Roy. Lond. Ophthal. Hosp. Rep.*, xiii, 1) give some interesting notes on this subject. Of the sixty cases, thirty were in males, twenty-seven were in females, and in three the sex was not given. Of the sixty cases, the growth occurred simultaneously, or with short intervals, in both eyes in twelve; in four others there was decided probability that the disease attacked both eyes; and in one case the affection of the second eye may have been glioma. Of those in which the disease was unilateral, the right eye was affected in sixteen cases, the left in twenty-seven cases, and in one case it was not stated. The disease was first noticed by the parents within three months of birth in nine cases; of these it was noticed at birth in five cases, and during the first five weeks of life in two cases; between three and six months in four cases; between six and twelve months in nine cases; during the second year in thirteen cases; during the third year in seven cases; during the fourth year in three cases; during the fifth year in four cases; during the sixth year in four cases; during the seventh year in one case; age uncertain in six cases. From these figures it appears that the growth becomes evident with greatest frequency during the first year. The authors have regarded as permanent recoveries only those cases in which reliable information was obtained that the patient was alive and well, and that no return of the disease had occurred three years after the removal of the eye or eyes. Of the sixty cases reported, eight may be regarded as permanent recoveries. In these cases the average time which elapsed between the discovery of the growth and the removal of the eyeball was four months. In sixteen fatal cases the average interval was fourteen months. Of twenty-two cases, the tumor recurred in the orbit in seventeen. In the remaining five, secondary growths were met with in the cranial bones, throat, palate, and in one case in the brain and spinal cord.

**An Ophthalmoscopy with Micrometer.**—Leroy (*Rev. gén. d'ophthal.*, October 31, 1891) has devised an instrument which contains within the dimensions of an ordinary ophthalmoscope the properties of a refraction ophthalmoscope and of an objective and subjective optometer, and which, in addition, enables the observer to measure objectively the elements of the fundus of the eye which are visible with the ophthalmoscope. It is composed essentially of two parts. 1. A refraction ophthalmoscope with three interchangeable mirrors, an ordinary concave mirror, a concave mirror of short focus inclined at an angle of  $45^\circ$ , and a plain mirror. 2. A positive eye-piece or ocular, at the principal focus of which is placed a micrometer, divided into tenths of a millimetre, photographed on glass. This eye-piece is furnished with a prism of total reflection of  $45^\circ$ , so placed as to reflect the image of the micrometer in the direction of the optical axis of the ophthalmoscope or visual line of the observer. A screw with a large button regulates the displacement of the tube containing the micrometer and prism, so as to bring the edge of the latter toward the center of the pupillary field. Then the eye of the observer receives simultaneously the rays from the micrometer and from the fundus of the patient's eye. The properties of the instrument are as follows: 1. If the eye-piece is removed, we have a refraction ophthalmoscope. 2. The eye-piece and prism being in place, if the observer, fixing his attention on the micrometer, approaches the glass which enables him to see at the same time a well-defined image of the fundus, this glass represents the patient's ametropia. If, during this examination, the observer accommodates, he is immediately warned of it by an indistinctness in the image of the micrometer, and he must then fix attentively the latter in order to bring his accommodation to a state of rest. 3. If the prism is turned  $180^\circ$  so that the rays of the micrometer are turned toward the patient, the glass which enables the latter to see the micrometer distinctly under the known existing conditions will be the glass which corrects his ametropia. 4. The most interesting property is that of enabling the observer to measure the visible elements of the fundus. After having arranged the micrometer in the suitable manner by turning it in its frame, the desired measure is obtained by reading the number of divisions which cover the dimension sought for. Thus can be measured the caliber of the vessels, the

papillary diameter, the dimensions of a staphyloma, of a hæmorrhage, of an exudation, or of a chorioidal lesion.

**Affections of the Vision in Parkinson's Disease.**—Galezowski (*Rec. d'ophthal.*, February, 1891) draws the following conclusions from his observations: 1. In Parkinson's disease vision is usually intact, and when it is affected the symptoms are slight and never progressive. 2. Generally the eyes are fixed, and the excursive movements are but slight. 3. The upper lids of both eyes are generally lowered, and only cover about half of the eyeballs. 4. The lids, in spite of their immobility, show a slight trembling which is difficult to recognize, and this same tremor is at times to be seen in the eyeballs also. 5. Vision is usually intact, but in rare cases there is a unilateral amblyopia without ophthalmoscopic lesion, with a narrowing of the visual field throughout about three quarters of its extent. 6. The immobility of the head and eyes renders all work difficult.

**The Simplification of the Operation for Extraction of Cataract.**—Dimissas (*Rec. d'ophthal.*, March, 1891) recommends the following rules: 1. The easy and more extensive laceration of the capsule with the knife should replace the employment of the capsulotome, (1) because the operation is thus shortened; (2) because the source of possible infection is suppressed, as the capsulotome is a difficult instrument to clean. 2. The extrusion of the lens, following so soon after the completion of the incision, is easily managed, and the removal of the cortex is soon accomplished. Hence secondary cataracts are rare. 3. The procedure thus preventing especially all late inflammatory accidents, the first dressing may be left on the eye for a longer period.

**Herpes Corneæ in Influenza and its Treatment by Pyocetanin.**—Galezowski (*Rec. d'ophthal.*, April, 1891) thinks that the healing of this form of keratitis may be facilitated by the following means: Irrigation of the cornea with a solution of yellow apyoin, and the administration of large doses of the sulphate or hydrobromide of quinine. He uses a solution of apyoin or pyocetanin in the strength of one centigramme to the gramme of distilled water, and bathes the cornea with it five or six times a day. He states that this treatment gives excellent and very rapid results.

**Iritic Uveitis.**—Grandclément (*Rec. d'ophthal.*, May, 1891) thinks that this form of inflammation of the uveal tract resembles pulmonary pleurisy, and deserves a special name. He thinks it is caused by a special micro-organism, and that it is best treated by excision of a portion of the iris.

**The Indications for Suture of the Cornea and Sclerotic.**—Galezowski (*Rec. d'ophthal.*, April, 1891) thinks that suture of the cornea or sclera, or both, should be employed (1) in certain grave accidents following the operation for cataract; (2) in all lacerations and perforating wounds of the cornea; (3) in all wounds of the sclerotic. He has devised special forceps and special needles for performing the operation, which have no advantage over similar instruments long since devised and used for the same purpose.

**A New Operation for Congenital Ptosis.**—Gillet de Grandmont (*Rec. d'ophthal.*, April, 1891) describes his operation as follows: 1. After having seized the upper lid with a Snellen's forceps, the skin is cut through parallel to the free border of the lid, the incision being three or four millimetres from the border and about two centimetres and a half long. 2. Raise up the two cutaneous flaps and detach and excise the corresponding portion of the orbicular muscle, so as to expose the entire tarsus from the ciliary border to and including Sappey's orbito-palpebral muscle or tendon of the levator palpebræ. 3. Cut through the entire thickness of the tarsus, for an extent of two centimetres, parallel to the free border of the lid, and from two to four millimetres from it. 4. Describe a curvilinear incision, with concavity downward, extending from one end of the first incision of the tarsus to the other. This incision should extend through all the tissues of the lid, including the conjunctiva. 5. The upper or orbito-palpebral flap should then be stitched to the lower or tarsal flap by three sutures without touching the skin.

**The Curetting of the Lacrymal Sac.**—Despagnet (*Rec. d'ophthal.*, April, 1891) draws the following conclusions: 1. Whenever in a given case epiphora is caused by catarrh of the lacrymal sac, the alteration of the mucous membrane is the principal factor in the disease, and it should be modified by probing and astringent injections. 2. If this

treatment fails to produce favorable results, curetting the mucous lining of the sac is indicated, rather than any other operative procedure. 3. If the lacrymation coexists with an exaggerated dilatation of the sac, or mucocele, excision of a portion of the anterior wall should precede the curetting. 4. Curetting is also indicated in phlegmonous inflammation of the sac.

**Dermoid Cyst of the Internal Wall of the Orbit.**—Vignes (*Rec. d'ophthal.*, July, 1891) gives the following results of a macroscopical and microscopical examination of a case of this nature: 1. The seat of the pedicle of the cyst was the plano-frontal suture. 2. The presence of the cyst could only be explained by the foetal inclusion of the ectoderm within the fronto-maxillary fissure by the welding or union of the external nasal bud and the maxillary bud behind the lacrymal hiatus. 3. Neither fibrous nor any other band connected the cyst with the skin. 4. The diagnosis of similar cysts might be difficult, as they might be confounded with a lipoma, a fibroma, and even an osteoma. 5. Cysts develop more frequently on the external side of the orbit than on the internal.

**Tincture of Iodine in Infectious Ulcers of the Cornea.**—Chibret (*Rec. d'ophthal.*, September, 1891) thinks he has found in tincture of iodine the following necessary properties: 1. A powerful and general antiseptic action. 2. Energetic dialytic power. 3. Absence of formation of insoluble salts causing indelible opacities of the cornea. 4. Non-destructive effect on the cornea. He thinks his belief in the value of this drug has been fully justified by the results, and he even recommends its use in corneal scars and opacities.

**The Visual Field in Epileptics and Mentally Deficient Patients.**—Lombroso (*Rec. d'ophthal.*, August, 1891) draws the following conclusions from his observations: 1. The visual field is remarkably limited in epileptics and idiots. 2. There is a constant irregularity at the periphery of the field, and the line of demarkation appears irregular and sinuous, sometimes forming actual peripheral scotomata of very inconstant location. 3. The field is more limited on the right side in the lower hemisphere, and on the left side in the upper hemisphere, thus forming a partial hemianopsia to the right below and to the left above. This he calls a partial heteronymous vertical hemianopsia. 4. In some cases there was an extreme limitation of the field due to neuro-retinitis. 5. In all, the field for color was limited, its form following constantly that for white, but more or less regularly. 6. The field for blue and that for red cross at different peripheral points. 7. In almost all cases the ophthalmoscopic examination was negative. 8. The visual acuity was entirely independent of peripheral vision.

**Congenital Amblyopia.**—Martin (*Ann. d'oc.*, January-February, 1891) thinks that instead of placing the cause of congenital amblyopia in an anatomical malformation or in the neutralization of a diffuse image by the sensorium, we should regard it as the consequence of a special anæsthesia of the retina. The rays which are not focused are incapable of developing in this membrane the degree of sensibility necessary for the occasion. In astigmatic amblyopia the visual trouble is dependent on a partial anæsthesia of the retina. In a large number of cases of congenital amblyopia the retinal anæsthesia is not the only existing factor, for the visual defect is often increased by lack of use (unilateral amblyopia) or by a retinal congestion (bilateral amblyopia). The amelioration arising from the use of an eye which has been long inactive is the greater the less pronounced is the visual defect due to retinal anæsthesia.

**The Indications for Simple Resection of the Optic Nerve.**—De Wecker (*Ann. d'oc.*, March-April, 1891) considers that the most important point is the removal, not only of the eye, but of as much as possible of the optic nerve also, with prolonged and repeated disinfection of the remains of the nerve and contents of the orbit. The next most important indication is simple enucleation, without resection or disinfection. The third indication, if enucleation is declined by the patient, is the resection of a large piece of the intra-orbital portion of the nerve, followed by a disinfecting irrigation prolonged for some minutes. Finally he considers the subject of simple local disinfection by introducing a few drops of sublimate solution within the shell of the eye. He, however, regards the simple resection of the optic nerve as a certain means of prevention of the occurrence of migratory ophthalmia.

**The Question of Sympathetic Ophthalmia.**—Abadie (*Ann. d'oc.*,

March-April, 1891) thinks that when an eye has been injured it may, according to the nature of the infectious agent, become the seat of phlegmonous inflammation, or it may be destroyed by infectious irido-chorioiditis ending in atrophy; or there may result a sympathetic ophthalmia. In the first case the cauterization of the wound with the galvano-cautery is the only method of preventing suppuration. In traumatic ophthalmia (infectious irido-chorioiditis) the cauterization of the wound and intra-ocular injections may save the injured eye and prevent sympathetic ophthalmia. Finally, even when a sympathetic ophthalmia has recently occurred, if the injured eye is not entirely lost, cauterizations and intra-ocular injections should be tried. If, in spite of this treatment, repeated if indicated, the sympathetic ophthalmia does not recede, enucleation must be done.

**The Pathological Anatomy of Buphthalmia.**—Kalt (*Ann. d'oc.*, May-June, 1891) draws the following conclusions from his investigations: 1. Buphthalmia is the result of a very chronic irido-chorioiditis, which causes a progressive obliteration of the vessels of the uveal tract. 2. There results an intra-ocular supersecretion, the origin of which is probably not in the cells covering the ciliary processes, as most of these have been destroyed. 3. The existence of this supersecretion must be admitted, since the channels of excretion are found considerably enlarged. Hence we have to deal with glaucoma by resection. 4. Eserine lowers the increased tension to the normal state.

**General Considerations on Squint; the Innervation of Convergence.**—Parinaud (*Ann. d'oc.*, September, 1891) draws attention to the singular fact that tenotomy has served to establish a theory which is erroneous—namely, the muscular theory of the causation of squint. Most ophthalmologists regard the ocular affection as a physical phenomenon relating solely to the eye and its muscles, without considering the influence of the brain in the matter. But the influences which produce strabismus all rise in a disturbance of innervation. This, however, is a special innervation, that of convergence, and the solution of the question of strabismus can not be found until this innervation is recognized and demonstrated. He lays down four main propositions, viz.: 1. Concomitant squint should be regarded as a vicious development of the binocular visual apparatus. 2. Whatever impedes binocular vision may become a cause of strabismus, and the younger the subject is, the more likely is this cause to prevail. These causes are of two kinds, one set being located in the eye and the other in the brain. The ocular causes are errors of refraction, mechanical obstacles to motility, the prolonged exclusion of one eye, etc. The cerebral causes are those affections which impede the development of the brain in infancy. Heredity is also a factor in strabismus. This is not only shown by transmission of errors of refraction, but also by a defective cerebral disposition to binocular single vision. 3. All causes of strabismus, whether peripheral or central, act by modifying the innervation of convergence, which is essentially the innervation of binocular single vision. All that is attributed to weakness or congenital preponderance of certain muscles should be attributed to a hereditary defect of convergence. 4. The primary causes of strabismus should be distinguished from those modifications which arise later. Parinaud concludes by affirming that: 1. There is a special innervation of the ocular muscles for convergence. 2. The relations between convergence and accommodation are established by means of this innervation. 3. The change which should be established between these relations in ametropic subjects, so as to admit of binocular single vision without correction of the ametropia, is produced by the brain.

**The Mode of Development of Cyclopia.**—Darceste (*Ann. d'oc.*, September, 1891) concludes that in cyclopic monsters the production of a single eye, the changes in the structure of the mouth, the atrophy and abnormal situation of the olfactory apparatus, the arrest of development of the vesicle of the hemispheres, are all the result of arrest of development of the anterior cerebral vesicle. Cyclopia may be produced in two different ways: 1. By a simple arrest of development, which may affect the anterior cerebral vesicle as well as any other organ. 2. By the compression exerted by the amnion arrested in its own development.

**Bacteriological Researches in Cataract.**—Dubief (*Ann. d'oc.*, September, 1891) formulates the following conclusions from his investigations: All the surrounding conditions being rendered aseptic, if micro-

organisms exist in cataracts, they are few in number. The lavage or irrigation of the lens enables us to state that if the microbes exist, they occupy the surface of the organ, and this particular location enables us to assume an accidental contamination. Even the variety of the micro-organisms found enables us to affirm that their origin is outside of the lens, and that they have been gathered there by the lens itself or by the instruments used in the operation of extraction.

**The Anatomy of Chronic Inflammation of the Conjunctiva.**—Muter-milch (*Ann. d'oc.*, October, 1891) concludes from his investigations that the only constant anatomic-pathological phenomenon accompanying all cases of chronic inflammation of the conjunctiva, and which at the same time is the cause of the production of pannus, the only characteristic sign which should serve as datum for a rational classification, is the alteration of the epithelium. The pathological process attacks only the cells nearest the conjunctival surface, while the deeper cells remain normal throughout the whole duration of the disease. There are three stages of the process: 1. The stage of proliferation. 2. The stage of superficial destruction. 3. The stage of total destruction.

**The Anomalies of Convergence.**—Von Millingen (*Ann. d'oc.*, August, 1891) offers the following propositions for consideration: 1. Paresis of voluntary convergence is that form which is shown by the impossibility of converging on a very near point without the production of latent divergent squint. Binocular vision exists, though with somewhat difficult accommodation and accompanied by asthenopia. 2. Paresis of visual convergence includes those cases in which, in spite of excellent binocular vision, the power of voluntary convergence on a very near point being preserved, accommodative convergence as a regular act during ordinary vision is abolished, and gives rise to crossed diplopia with divergent squint. 3. Paralysis of visual and voluntary convergence is shown by the entire loss of the power of convergence, whether voluntary or with accommodation. If these propositions are true, we must conclude: 1. That the centers of convergence are connected with the optical as well as with the cortical region, and that the communication with one of these centers may be entirely intact, while that with the other is interrupted. 2. That we must distinguish between visual and voluntary convergence, and must be able to tell in a given case which of the two is paralyzed.

**Lymphatism and Trachoma.**—Truc (*Ann. d'oc.*, August, 1891) draws the following conclusions from his investigations: 1. Lymphatism is the "clinical soil" of trachoma. 2. Lymphatism favors the development and modifies the general appearance of granular ophthalmia. 3. Lymphatism, in its different grades, constitutes the various granular formations which may be classified as lymphoid, fungoid, sclerosed, or fibroid. 4. Lymphatism is the principal factor of granular lesions of the cornea. 5. Lymphatism is also the "clinical soil" for phlyctenular or scrofulous ophthalmia. There are certain morbid combinations in which granular ophthalmia exists with phlyctenular, scrofulous, or lymphatic ophthalmia, and forms granulo-lymphatic ophthalmia. 6. Lymphatism is the "clinical soil" for certain cases of lacrymal keratitis. There are certain morbid conditions in which granular ophthalmia, together with lacrymal ophthalmia, unite to form a granulo-lacrymal ophthalmia. 7. Lymphatism favors the infection and contagion of trachoma in proportion to its degree.

**Two Cases of Total Achromatopsia.**—Querenghi (*Ann. d'oc.*, November, 1891) has revised the histories of three cases published by Landolt and two of his own, and draws the following conclusions: 1. In all the five cases of total achromatopsia there was considerable reduction of visual acuity, which did not exceed one tenth for distance. 2. In four cases nystagmus was present. 3. There was intense photophobia in three cases. 4. The red of the spectrum and deep red in all cases appeared as black. The other colors appeared as achromatic lights of different intensity, according to the tone and degree of saturation. 5. Next to white, yellow gave the most intense luminous sensation. 6. Those cases which recognized the entire spectrum as a source of light, all put the line of greatest brilliancy in the yellow.

**Eye Disease of Miasmatic Origin.**—Bagot (*Ann. d'oc.*, November, 1891) reports the three following cases: The first was that of a young man, aged fifteen, a mulatto, who had a severe attack of miasmatic fever of the congestive type with intestinal complications. Immediately after the height of this attack the vision became affected, and three

months later there was a soft cataract in each eye. These being removed, normal vision was restored. The *second* case was that of a mulatto woman, aged sixteen, who had a very severe attack of paludal fever, with cerebro-spinal symptoms, loss of consciousness, convulsions, and delirium. The vision became affected, grew steadily worse, and in nine months there was a fully developed soft cataract in each eye, which was removed by operation and normal vision was restored. The *third* case was that of a young white girl who had an attack of pernicious miasmatic fever, with delirium, convulsions, and loss of consciousness. On regaining consciousness, the child saw everything red for twenty-four hours, and then became rapidly blind from retinal hæmorrhages and atrophy of the optic nerves.

**The Introduction of an Artificial Vitreous Humor into the Scleral Cavity.**—Morgan (*Arch. of Ophthalm.*, xx, 1) reports six cases in which he has performed this operation. The opening in the eye was enlarged horizontally by removing two triangular pieces of the conjunctiva and sclerotic, thus changing a nearly circular opening into a lozenge. The hæmorrhage continued about an hour and a half, and the "artificial vitreous humor" was not introduced until it had ceased. A solution of corrosive sublimate (1 to 5,000) or a hot saturated solution of boric acid was used as an antiseptic. Some of the patients experienced no pain, while others had but little pain or discomfort. The wound was closed with six sutures of fine silk. Some of the patients have worn their artificial eyes for one or two weeks without removal, and the conditions in all six are satisfactory and appear to be permanent.

(To be concluded.)

## New Inventions, etc.

### A NEW ATTACHMENT FOR ASPIRATORS OR SYRINGES.

By H. D. TAGGART, M. D.,  
AKRON, OHIO.

THE attachment consists of rubber tubing fashioned as shown in the accompanying cut. It is operated by compressing with the fingers at 1 and 3 alternately. It will readily be seen that a cavity may be drained and flushed through these tubes rapidly and with less pain than if the ordinary stop-cock were used, as the needle or cannula may be perfectly steadied during the working of the syringe. The tubes are easily cleaned. They are made by George Tiemann & Co., New York.

These gentlemen also manufacture an improved syringe piston, which will be appreciated by all who desire a syringe ready for use at any moment. It is made of ebonite and kangaroo. Some of its good points are: Almost a negative degree of friction; no "jumping"; it does not dry, shrink, or become moldy, however long in disuse. It is very simple in construction, but works better than any of the expensive contrivances designed to accomplish the same thing.

## Miscellany.

**Laceration of the Cervix Uteri and Pelvic Inflammation.**—Emmet's operation for the repair of laceration of the cervix and his ideas of the

pathogenic features of that injury have been so much decried, especially in Great Britain, that it may be wholesome if attention is called to the following article, entitled *The Pathogenesis and Treatment of Oophoritis*, by Dr. Robert Bell, senior physician to the Glasgow Hospital for Diseases peculiar to Women, published in the February number of the *Edinburgh Medical Journal*:

If we carefully look into the history of oophoritis and subsequent hyperplasia of the ovary, we shall probably be led to the conclusion that these conditions, as a rule, are secondary to a morbid condition which has previously existed in the uterus; that the ovarian mischief, in the majority of instances, is dependent upon disease which has for some time before been, and is no coincident with that in the neighboring organ. What, however, is of much greater consequence for us to be assured of is that, if the morbid process has not proceeded too far in the ovary, the organ can in many instances be re-established in health *pari passu* with the recovery of the uterus. The question naturally arises in these circumstances, What is the *modus operandi* of the disease process? So far experience has distinctly taught me that when oophoritis exists it has very frequently, if not always, been preceded by endometritis. However, I do not pretend to be in the position to affirm that the disease may not sometimes arise *de novo*; but that the cases where this occurs are few and far between is a subject on which I can entertain no doubt, and it is because of this conviction that I have been encouraged to persevere with the treatment advocated in this paper in cases which, for a time, seemed to be quite intractable, but which, though trying one's patience to the utmost, eventually yielded and recovered. It might possibly be demonstrated that the ovaries are more frequently affected when the cervix is most seriously involved, but then we must bear in mind that this portion of the uterine canal is liable to suffer to a greater extent than the upper portion, as the whole of the acid discharges which are secreted there in endometritis must of necessity pass over the cervical mucous membrane, and aggravate the disease that already affects and has induced hypertrophy, and probably exoriation of it.

The fact, however, which compels me to suggest that endocervicitis has more influence as a factor in inducing ovarian irritation than disease of the corpus and fundus uteri is that, on passing the applicator through that portion of the canal, the pain consequent upon doing so is generally referred to the affected ovary, demonstrating, I hold, a direct nervous connection therewith. Then, again, we invariably find that when oophoritis supervenes upon a laceration of the cervix, that it is the ovary of the affected side which becomes involved, and the ovarian disease does not yield to treatment until the laceration is repaired, or the pendulous portions of the injured cervix removed. This coincidence, however, may be due to the fact that the pathological condition of the cervix has given rise to disease of the uterus as a whole, and that the health of this organ can not be restored until the integrity of the cervix has been re-established.

We are all aware of the intimate relationship of the uterine to the ovarian circulation, and it is only natural to conclude that if the circulation is interfered with in the uterus, which undoubtedly is the case when endometritis is present, it must react upon the ovaries, whose affluent and effluent vessels are continuations of those supplying the uterus.

There is, however, another factor which plays a most important part in the pathological process, that being the effect of the uterine irritation upon the sympathetic nervous apparatus, thus further influencing the circulation through the medium of the vaso-motor system. Any persistent morbid process, like that which is present in endometritis, must necessarily have a marked effect upon the sympathetic ganglia from whence the vaso-motor filaments supplying the uterus are derived, and as the ovaries and uterus are supplied from the same source, it stands to reason that the circulation in the ovaries by reflex influences must be materially affected. The result is that the hyperæmic condition of the uterus is reflected to the ovaries, producing a congested condition of these organs. Such being the case, it is only natural to conclude that, if the original morbid condition is removed, the secondary disease will also subside; and such in point of fact is really what takes place, provided the disease in the ovaries has not advanced too far. It is, of course, difficult to decide right off when a case has advanced be-

yond the reach of medical treatment and crossed the barrier beyond which resolution will not be assured.

I have, however, taken cases in hand when the ovary has been enlarged to the size of a tennis ball, and have obtained most satisfactory results after from three to six months' treatment. If cystic degeneration of the organ has commenced, I need hardly say no treatment short of operation will prove of any avail. The instances of ovarian disease, however, which we constantly meet with, are, as a rule, so amenable to the treatment I have adopted that it is hardly fair to the patient not to give her at least the chance of being relieved by this method, and thus avoid an operation which, even if it be successful, can not but be humiliating to her.

With the view of demonstrating that the conclusions I have arrived at are correctly based upon fact, let me devote a few moments to the consideration of a lacerated cervix (say on the left side) and its effects. Why is it, if this has occurred and the ovary becomes affected, that it is invariably on the side upon which the laceration exists? How is it that the right ovary remains intact? In the light of the present day, surely it is quite unnecessary for me to enter into any explanation on this point. I have seen a considerable number of instances of ovarian disease, a vestige of which did not exist prior to a confinement, develop rapidly after that event, and in each case a laceration of the cervix was discovered on the side of the affected organ.

Moreover, notwithstanding what some authorities may assert, the ovarian affection in every instance disappeared very rapidly after the rent in the cervix had been repaired, and not till then. There is not the slightest doubt that injury to the cervix is a fruitful source of disease, not only in the uterus itself, but also in the ovary of the affected side. Repair the cervix, therefore, and restore its health, when, in a short time, if the disease has not advanced too far, the ovarian mischief will subside and entirely disappear. If, on the other hand, the disease of the cervix is idiopathic, the development of symptoms and of sequelæ will not be so rapid, and possibly the ovaries may escape altogether. If, however, degeneration of the cervical tissue has supervened and erosion taken place, from which surface a purulent discharge is given off, then it is probable that the ovaries will become secondarily affected, and their health will only be restored if the primary disease is first removed. We should also bear in mind that, if cervical disease is permitted to exist, it is not likely to end there, but will spread by continuity of tissue to the whole extent of the endometrium, and possibly to the tubes also. The walls of the uterus in consequence will become hypertrophied and softened. Flexions will thus frequently be induced, and interference with the venous circulation will arise which will tend to aggravate the original mischief.

Now, to proceed to the treatment of such cases, it is hardly necessary for me to state that in the event of the endometrium having become affected, it will be essential, before the cervix can be permanently relieved, that the condition of the former be simultaneously attended to. Otherwise, as I have before remarked, the acrid discharges, which invariably have their source in endometritis, would continue to flow over the cervical mucous membrane and maintain the irritation which previously existed, and this in spite of all the treatment that might be applied to it *per se*.

To illustrate my method of treating such cases, I will detail two typical instances of oophoritis—one depending upon laceration of the cervix, the other upon idiopathic disease. I take these two cases because both occurred in young women; and there can be no doubt of their history, as I have known the patients for over fifteen years, and have attended them during a period which extends for a considerable time prior to and after their marriage, both before and after they were the subjects of ovarian disease, and also after this had been removed.

Mrs. S., after a somewhat tedious labor, was delivered of a boy considerably above the average size. She made a good recovery, but some six months afterward complained of a severe pain in the left side, which was aggravated on any exertion. There was a feeling of bearing down and a copious vaginal discharge of a muco-purulent character. Over the site of the left ovary there was considerable pain on pressure. On a vaginal examination being made, the cervix was discovered to be lacerated on the left side, the rent extending throughout the whole of

the vaginal portion. Endometritis also existed, and the uterus was retroflexed and hypertrophied. The course adopted was to treat the endometritis by the intra-uterine application of iodized phenol and vaginal tampons of the glycerin of alum and boracic acid. When the endometritis had subsided somewhat, trachelorrhaphy was done—with the result that in three months the uterus had regained its health, while the ovary returned to its normal size, and all pain and inconvenience had ceased.

The other case is that of a young married lady, Mrs. H., who had suffered intensely from dysmenorrhœa and copious leucorrhœa for a considerable period previous to her marriage. Though I did not make an examination then, I was convinced that endometritis was present, this having been induced by attending dancing parties night after night, quite irrespective of the fact that frequently she was menstruating at the time. Menorrhagia also existed, which was induced by the same reckless conduct. After marriage her symptoms became aggravated, and she came to me complaining of intense prostration, both mental and physical, while pain on the least exertion was very acute over both ovaries and in the back. Defecation was very painful, and there was a profuse muco-purulent discharge. On examination, both ovaries were found to be enlarged and hypersensitive to touch. The uterus was retroflexed, and there was metritis. Dyspareunia also existed to a prohibitive extent. She was put under treatment, which consisted of the weekly application of iodized phenol to the endometrium, and each time the uterus was restored to its normal position, and retained there by means of tampons soaked in glycerin of alum and boracic acid, which were renewed in three days and fresh ones inserted. In less than four months all trace of discomfort had disappeared; the uterus remained *in situ*, and the ovaries were reduced to their normal size, and within a year afterward she became pregnant.

There would be no difficulty in citing any number of additional cases to illustrate what I have endeavored to describe as one of the most potent factors of oophoritis, and to demonstrate what happy results can be attained by the employment of suitable measures for the restoration of the uterus when disease of this organ is concomitant with oophoritis.

I do not, however, wish it to be inferred that I hold oophorectomy can always be avoided; but at the same time I can not refrain from stating as my firm conviction that in many instances it may be avoided if the treatment I advocate receives an honest trial.

**Laboratories of Hygiene.**—On the occasion of the opening of the new laboratory of hygiene of the University of Pennsylvania, on Monday of this week, an address was delivered by Dr. John S. Billings, of the army. By the courtesy of the editor of the *Medical News*, in which the address is to be published in full, we are enabled to give the following extracts:

Laboratories planned and fitted for public use, offering to any one who is able and willing to pay a moderate fee and to submit to a few simple regulations, not only opportunities for learning the details of the processes carried on therein, but facilities and means for making special research as he could only obtain otherwise at great expense and loss of time—such laboratories, I say, are all of comparatively recent date.

It is not yet twenty years since the first separate institution of this kind was established for hygiene—and even now there are not more than a dozen such laboratories, specially built and fitted for their purpose, in existence throughout the world. Of these the best known is probably that of the University of Munich, under the direction of Professor Pettenkofer, while the largest is that of Berlin.

This laboratory is the first structure of its kind erected in the United States, and it therefore opens a comparatively new field of work in this country. What is the nature of this field and what are its boundaries?

The object of hygiene is to preserve and to improve health, and there are few matters affecting the physical, intellectual, emotional, and moral condition of man as an individual, or of men in communities, that may not come within the scope of its investigations. The destruction or avoidance of causes of disease is but a part of its objects—it is at least equally concerned with the means of making a man bet-

ter fitted to resist these causes. "That kind of health," says Montesquieu, "which can be preserved only by a careful and constant regulation of diet is but a tedious disease." Disease, like health, is a vague term, including widely different and often very complex conditions, processes, and results, which must be observed, classified, and described in such a way that different men, widely separated in space and time, may know that they are seeing the same things, and thus may have the benefit of each other's experience.

In its scientific aspects, then—those which relate to definite and precise knowledge—hygiene rests largely on physiology and pathology, the third leg of the tripod being formed by vital statistics; while in its practical aspects it must rest on chemistry, physics, and the data of sociology and politics.

At any given time, therefore, its scope and practical value must depend largely upon the breadth and solidity of the foundations which these various branches of science can provide for it. The opinions of the medical faculty of Paris as to the causes of the "black death," and the advice which they gave as to the means for lessening the "great mortality," absurd and preposterous as they now appear to us, were yet fully in accord with the knowledge and opinions of the time.

At the beginning of this century physicians did not distinguish with any certainty between typhoid, typhus, and malarial fevers, or between consumption and various other chronic diseases of the lungs, and until this was done investigations into the causes of these affections were necessarily almost fruitless.

When, however, a clew is once given to the student of causes, he may be able, by detecting differences in these causes, to call the attention of the pathologist to differences in the results, and thus the bacteriologist, by proving specific differences in micro-organisms, all of which produce fever, suppuration, etc., induces closer study of details of cases by physicians, and the recognition of new and more clearly defined groups of symptoms and results, or, in other words, of new diseases.

We live in an age of specialization. Progress in science, as a whole, depends upon special progress in each of its branches. Our present knowledge of physiology depends largely upon the perfection of electrical methods. Pathology and pathological bacteriology are now waiting for increase of knowledge in organic chemistry. The law of evolution applies to this as it does to modern industrial progress.

The physician deals with sick men, and his first question is, What is the matter with this person? That is, what group of symptoms does he present, and to what derangement of his mechanism are these due? The hygienist deals with two sets of problems—the first relating to men who are not sick, and how their health and vital resistance power are to be not only preserved, but improved and strengthened; the second relating to sick houses, feverish blocks or wards, infected localities—where the first questions to be solved are: What are the causes of this condition of things? How have they found entrance? Are they still acting?

In the investigation of causes he must consider not only the immediate or exciting, but also the remote or predisposing; not only those which are preventable, but those which, with our present knowledge, are unpreventable; and thus it is that heredity, race, local meteorology, occupation, and many other circumstances must be studied by him, as well as the effects of food, clothing, habitation, poisons, and viruses.

The recent advances in our knowledge as to the action of certain micro-organisms in the production of disease in animals and man have been largely made by laboratory methods, and indicate clearly that the study of bacteria and microzoa, and of their development, products, and effects, must be an essential part of the work of a hygienic laboratory, which should provide the peculiar arrangements and apparatus which are required for this sort of work. In fact, several so-called hygienic laboratories are simply bacteriological laboratories, the interest in this particular branch of investigation having, for the time being, overshadowed all others.

Our laboratory, however, must provide also the means for chemical investigations of air, water, food, sewage, secretions and excretions, and

the products of bacterial growth; for testing the effects of gases, alkaloids, and albumoses of various kinds upon the animal organism; for investigations in the domain of physics pertaining to heating, ventilation, house drainage, clothing, soils, drainage, etc.

Just at present research is being specially directed to certain minute animal organisms—the microzoa—such as are found in the blood in malaria and in the skin in certain diseases, and to immunity, especially to that immunity which may be artificially produced.

Experimental investigation is a slow process, and very uncertain in its results. An experiment may be conceived which seems as if it would give important results. The experiment itself would require only a few moments or a few hours if all the apparatus were ready to produce the required conditions, and to record in terms of weight and measure the results obtained. But to make this apparatus in the best form, and to provide the means of recording, may take a year or more, and in making this preparation a dozen problems will come up to be solved by other experiments.

You are pretty sure to discover something new, but by no means sure that it will be what you began to seek. Every discovery opens new questions and indicates new experiments, and the precise shape in which the work presents itself varies with place and season.

We can not foresee precisely the demands which will be made upon us, or which we shall make upon ourselves, but we do know that we shall want some large rooms in which a dozen or twenty men can be at one time taught how to investigate, working under the eye of an instructor; and also a number of small rooms, each fitted for the work of one or two men who have attained a certain amount of skill, and are engaged in original research. In all these rooms we shall at times need to use microscopes, gas-heating, and steam; there will be vapors and fumes produced; there will be delicate instruments scattered about, and the rooms must therefore be light, have abundance of gas, steam, and water, hoods and flues for conveying away fumes, and plenty of fresh air without dust.

Many of the things that will be seen through the microscopes will be rapidly changing form, and we shall need pictures as well as descriptions of their different shapes.

The most useful drawings for our purposes are those made by sunlight, and therefore we want photo-micrographic rooms.

We shall wish to test the merits of various articles of house-equipment, such as different patterns of steam radiators, traps, sinks, closets, etc., and for this purpose we must have places where they can be fitted and put into use.

We must know what other investigators in other laboratories, and many places besides laboratories, have done and discovered, that time and effort may not be wasted.

We must therefore have the books and journals in which these are recorded, which are already many, and coming rapidly. A small library and reading-room is therefore essential.

Much of the apparatus to be used must be either made or specially fitted and adjusted on the spot to meet special indications which it is impossible to foresee, and therefore we need a large workshop, with tools and appliances for working in wood, glass, and metal, and with power.

After describing the new laboratory, Dr. Billings continued as follows:

We hope that some increase of knowledge will be made here by the workers in the laboratory itself; but the main point to be kept in view is to provide well-trained, scientific, and practical men for other fields of labor. Dr. Mitchell has said that the true rate of advance in medicine is not to be tested by the work of single men, but by what the country doctor is. So, also—and even more so—advance in practical sanitation is not to be measured by laboratory records, but by what health officers and sanitary engineers are able to accomplish.

Even now we *know* much more than we *do*, and the skilled sanitarian too often finds himself in the position of the unhappy daughter of Priam and Ilecuba, who could foretell, but to no purpose.

This laboratory is fortunate in being closely connected with, and in the immediate vicinity of, a great medical school, and of great hospitals. As was said before, one of the essential foundations of sci-

tific knowledge of the causes of disease is minute and accurate diagnosis and pathology, and we are therefore in constant need of the best knowledge of leaders in these branches of medical science. The hospital is filled with specimens of the results of such causes, acting on the human body—from one point of view, Nature's experiments with poisons cunningly elaborated in the tissues of the body, or with viruses coming from without, upon blood and bone, muscle and brain. Much of the work of this new department will be connected with the results of these experiments.

The laboratory is also fortunate in being located in a great manufacturing city, where the effects of different occupations, of trades dangerous or offensive by reason of dusts, or of vapors, or of waste products, can be readily observed and the materials for study obtained. There is an immense field for a sanitary clinic here, and in the habitations, the streets, the water-supply, and the sewers of Philadelphia.

These clinics, however, can not, as a rule, be reported for the press, either lay or medical, since to do so would, to a great extent, defeat their object; the great majority of the sick in houses and manufactories must be considered as strictly private patients, and their affairs held as confidential. In the case of public institutions, or of public nuisances, a somewhat different rule may apply.

Practical hygiene is to play an important part in municipal government, to secure the best form of which is now one of the most urgent questions of the day. Many of the questions to be decided by city officials as to water-supplies, sewage disposal, etc., require expert knowledge to answer.

Of course, the subject of hygiene and the work of a university department devoted to the increase and diffusion of knowledge in sanitary science extends far beyond the experiments and demonstrations for which this laboratory is specifically fitted.

Bacteriology, chemistry, pathology, physics, and medical and vital statistics give us the foundations, but sociology and jurisprudence must also be studied in their relations to sanitation to obtain the best results.

It is in and to the home and the workshop that these results are to be applied, and he who aspires to be his brother's keeper must know how his brother lives.

Labor questions, education questions, maritime and inter-State commerce questions, and methods of municipal finance and government are all intimately connected with matters of personal and public hygiene, and economic consequences, as well as health, must be considered in the advice and regulations of the sanitarian.

I count it as fortunate, therefore, that there is a law school and a school of finance and political economy in this University to which the Department of Hygiene can look for advice and friendly criticism when these are needed, as they surely will be.

And now a very few words as to the needs of the laboratory. First of all, it needs men—men thirsting for knowledge, and fitted by previous training and education to come here and acquire that knowledge, not merely the knowledge that exists in books or that the teachers in this laboratory may possess, but that which is yet unknown, the weight of that which no one has yet put in the balance—the shape, and size, and powers for good or evil of things whose existence has not yet been demonstrated—men who will patiently and earnestly seek the answers to the questions, "What?" "When?" and "How?" in the hope that thus they may by and by obtain some light upon the more difficult problems of "whence?" and "whither?" even if they may never be able to answer "why?"

There are not many such young men whose tastes will be in the direction of these lines of research, and of these there will be very few who will have the means to support themselves while engaged in the work. We need, therefore, the means to help them in the shape of half a dozen fellowships, paying about five hundred dollars a year each, and granted only to those who give satisfactory evidence of capacity and zeal.

The second thing we want is a demand on the part of the public for really skilled, well-trained sanitary investigators and officials such as we hope to send out from here; we want a market for our product; we want the legislators of this and other States, and of our rapidly growing municipalities, to be educated to appreciate the importance and

practical value of such health officials, and to give the best of them employment.

Thirdly, the laboratory wants the co-operation and assistance of sanitary authorities and inspectors, and especially of those of this city and State.

It needs to know from time to time what they are interested in and are working at, to have the opportunity of showing to its students cases of special interest—sick houses, localized epidemics, special forms of uisance.

And, on the same principle and for the same reasons, it desires to have its attention called to special methods of heating, ventilating, and draining buildings, and especially public buildings, such as schools, hospitals, prisons, churches, and theatres, and to matters connected with the hygiene of manufacturing establishments and special occupations, methods of disposal of offensive or dangerous waste products, of protecting workmen against dusts, gases, etc.

In short, we want to know how these things are managed by the men who have a practical interest in them; and if, in our turn, we can suggest improvements, we shall be glad to do so.

Fourth, the laboratory wants a reference library as complete as it can be made, and always up to date. Many of the books and journals required must be purchased, and for this purpose a special fund is needed, but many of the works required can only be obtained by gift.

Thus we want all the reports of boards of health—State and municipal—of municipal engineers, water-works and water commissioners, park commissioners, etc.

We want the catalogues and circulars of all manufacturers of heating and ventilating apparatus, of plumbers' supplies and house fixtures, of electric and gas fixtures, of machinery and apparatus connected with water-supply and sewage disposal.

We want copies of plans and specifications of large buildings of all kinds.

And these things can only be obtained through the aid and goodwill of manufacturers, engineers, architects, and sanitarians all over the country; and this aid I venture to ask, feeling sure it will be granted by those who know what is wanted.

I will mention but one more special want to-day, and that is of means for the proper publication of illustrated reports and accounts of the work done in the laboratory.

In the mean time we must be patient, and not too eager to touch the fruit of the blossom that is not yet blown.

**The Anatomical Lesions of Amœbic Dysentery.**—At a meeting of the Johns Hopkins Hospital Medical Society, held on October 19, 1891, the proceedings of which are published in the *Johns Hopkins Hospital Bulletin* for January and February, 1892, Dr. Councilman exhibited the colon from a case of amœbic dysentery. The patient, a man, aged twenty-five, was admitted to the hospital on September 11th. Four weeks before admission he was attacked with pain in the abdomen and diarrhœa. He had six or seven fluid stools daily without much pain. The diarrhœa continued up to death, which occurred on September 21st. Most of the time the stools were of a greenish-yellow color, but several times in the last days of his illness they were almost entirely pure blood.

The body was that of a slightly built, tolerably well nourished man. The mucous membranes were very anæmic, the muscles pale and soft. On opening the peritoneal cavity there was no escape of gas. The parietal peritonæum was cloudy and covered with a very slight fibrinous exudation; there were a few ecchymoses scattered over it. The intestines were covered with the adherent omentum. On lifting this there was a free escape of gas from a cavity between the colon, the adherent omentum, and the coils of small intestine. The walls of the cavity were covered with a dirty yellowish membrane. It contained a quantity of putrid pus mixed with faecal matter. Outside of this cavity the coils of intestine were lightly adherent and there was some exudation, which was best marked at the line of adhesion. The exudation was fibrinous, rather gelatinous, and transparent. The mesenteric glands were slightly enlarged. The liver was firmly adherent to the diaphragm by fresh adhesions. The diaphragm on the right side extended to the fourth intercostal space; on the left to the lower border of the fifth rib.

In both lungs there were small foci of catarrhal pneumonia. The heart was normal.

The liver was large,  $24 \times 19 \times 8$  ctm., and weighed 1,892 grammes. The capsule was smooth. The color was a pale brown and the lobules were only visible in places. Scattered over the surface there were numerous small, white, opaque areas which were not surrounded by a zone of hyperæmia and not elevated above the surface. On section, small areas similar to those on the surface were found scattered through the organ. They varied in diameter from 1 to 5 mm. A dry caseous-like material could be squeezed from them, leaving a ragged wall.

The spleen, kidneys, pancreas, and adrenal glands were normal.

The large intestine was generally adherent by fresh adhesions. The cavity mentioned between it and the adherent loops of small intestine communicated with the lumen by a ragged opening 1 ctm. in diameter. The entire intestine was soft and tore easily on attempting to remove it. Its walls were thickened and it was greatly dilated, the average circumference being 14 ctm. It contained numerous ulcers and extensive sloughs from the cæcum to the anus. In the cæcum there were numerous round elevations with a small opening on the surface. There were also large irregular ulcers filled with a grayish, transparent material, on removal of which the muscular coat was seen. In the transverse and descending colon and in the rectum there were large irregular ulcers covered with dark sloughs. On removal of the sloughs the transverse muscular coat was laid bare, and in places the ulceration had extended through this to the longitudinal muscular coat or to the peritonæum. All the ulcers were greatly undermined. The coats of the intestine were thickened and œdematous. There were elevated ridges which often passed from one ulcer to the other, and they contained the same whitish transparent material as the ulcers. Numerous actively moving amœbæ were found in the intestinal ulcers, in the peritoneal exudation, and in the liver abscesses.

This case, the speaker said, was of interest from a number of points of view. The history showed a much more acute illness than in the other cases seen in the hospital, and there was not the intermittence which was so marked a feature in some cases. The abscesses of the liver differed from those in other cases in their great number, their small size, and their general distribution. Were it not for their size they might be taken for tubercles, the dry contents being more similar to the caseous material of a tubercle than to the contents of an abscess. In this case there could be little doubt that the amœbæ must have reached the liver by the blood-vessels and not by the peritonæum. In most cases the situation of the abscesses seemed more easily explained by supposing that the amœbæ had passed into the liver from the peritoneal cavity.

On examination of the tissues after hardening in alcohol, the liver abscess contained cell detritus, and at the edges there was a considerable degree of purulent infiltration. There were numerous foci of necrosis extending from the abscess and scattered through the liver. There were numerous amœbæ in the abscess contents.

In the ulcers in the intestine there were numerous amœbæ, both in the material in the ulcer and in the surrounding tissues. The character of the ulcers was typical of this form of dysentery.

Particular attention was paid to the lymph-glands. Numbers of those in the mesocolon were examined. Some of these were adherent to the intestines, and the ulceration had almost extended to them. In none of them were any amœbæ found. The only alteration consisted in a slight hyperplasia and a marked increase in the large cells of the sinuses.

In the study of the tissues there had been in general the best results after hardening in alcohol and staining the sections with an aqueous solution of safranin, although other methods would give some results not attainable by this. The amœbæ were better preserved by hardening in Müller's fluid, but this did not give such good results for the tissue of the intestine. The safranin stained the nuclei of the amœbæ and made their recognition easier. Under any circumstances the amœbæ might easily be overlooked, or the large swollen cells in the submucosa and in the sides of the ulcers might be mistaken for them. They could best be recognized after this staining by the marked vesicular type of the nucleus. It appeared generally as a bright stained ring with small knob-like projections on the inside. The nucleus did not

stain in hæmatoxylin or carmin or in any of the aniline fluids generally used. In specimens stained by the Weigert method, here and there a faintly stained nucleus could be found, but they were nearly all decolorized.

**The Rush Medical College, Chicago.**—The registrar, Dr. E. Fletcher Ingals, announces that a *concours* will be held at the college, beginning on Tuesday evening, March 1st, for the purpose of filling the positions of lecturer on anatomy and on materia medica and therapeutics in the spring faculty. The spring course begins on March 31st, directly after the close of the regular term, and continues for two months with a class of from 250 to 300 students, thus affording an excellent opportunity to exercise their skill as teachers.

It is the policy of the college, so far as practicable, says Dr. Ingals, to fill vacancies in the regular faculty from the corps of spring instructors. Nine of the present members of the regular faculty have been selected in this way.

The *concours* will consist of twenty-minute lectures by each of the applicants before the faculty, students, and local profession upon subjects pertaining to their branches, which will be furnished by the professors of anatomy and of materia medica and therapeutics a week before the contest.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

## Original Communications.

RESECTION OF THE POSTERIOR BRANCHES  
OF THE FIRST THREE CERVICAL NERVES FOR  
SPASMODIC WRYNECK;

WITH REPORT OF A CASE.\*

BY CHARLES A. POWERS, M. D.,

SURGEON TO THE OUT-PATIENT DEPARTMENT, NEW YORK HOSPITAL.

IN February, 1891, Mr. R. was sent to me by Dr. R. W. Amidon, to whom he had been referred a few weeks previously by Dr. F. Huber, for an opinion regarding a spasmodic affection of muscles of the neck. The patient was a heavily built, muscular man, of thirty-seven years. He had never suffered with syphilis, rheumatism, or other constitutional disease. He had been, from boyhood, excessively "nervous and restless," starting violently when suddenly surprised, and trembling at the slightest injury or fear of danger. His father had always manifested the same nervous conditions, and in a marked degree. Two years and a half previously he had first noticed a slight twitching of the muscles of the right side of the neck. This at that time was confined to a very moderate spasm, which carried the head to the right side. It was manifested only when he was suddenly startled or when he was much fatigued. These spasms gradually increased, however, both in frequency and in degree, and when he came under observation they were very marked. He had been given various drugs, electricity, and the like, by several different physicians, no measures being attended by permanent improvement. He was subjected to medical treatment by Dr. Amidon, and, this being without effect, he was referred to me, as said, for operative procedure.

The patient presented a rather senile look, stooping, and throwing the head well forward. When left to itself the head was spasmodically rotated to the right to its fullest extent. The patient could carry it back by pressing the chin over with the hand, but when the restraining force was removed it was immediately jerked back to its rotated condition. These spasms were constant during the day, but were worse when the patient was fatigued, irritated, surprised, or among strangers. The right hand was constantly upon the chin, and the patient was unable to use it in work or even at table. The right shoulder was not elevated, there was no spasm of the muscles of the left side, and the right trapezius, sterno-mastoid, and scalenus anticus seemed free from implication. The patient's neck was large, thick, and short; it seemed somewhat fuller on the right side, posteriorly, than on the left.

The spasmodic movement seemed to be a rotation of the atlas upon the axis. When it took place an increased fullness could be felt in the region just below the occiput and covered by the trapezius, although no contraction could be perceived in that muscle. The patient himself said that he "felt jerks in the deep muscles at the back of the neck." After very careful examination Dr. Amidon considered the affection to be confined to the posterior rotators, and recommended division or resection of the nerves supplying them.

I had but very recently read an article † by Dr. W. W. Keen, of Philadelphia, in which he described in detail the steps of an

operation formulated by him for the division of the posterior branches of the first three cervical nerves.

After familiarizing myself with the anatomy of the part by dissection on the cadaver,\* I proceeded upon the patient as follows: The occipital region was shaved and the parts were prepared in the usual way. The man was anæsthetized and placed flat upon his abdomen, the head projecting over the end of the table, and so held that the external occipital protuberance was in a straight line with the vertebral spinous processes. A three-inch transverse incision was made at the back of the neck, beginning at the median line an inch and a quarter below the external occipital protuberance and running forward. This was subsequently enlarged until it measured four inches and a quarter in length. The parts were divided through the trapezius and the posterior border of the splenius, until the complexus was reached and recognized, the trapezius being dissected up from it. After some difficulty the occipitalis major nerve was found at the upper part of the complexus and outside of the intramuscular aponeurosis of this muscle. Preserving the nerve, the complexus was divided transversely, after which the nerve was followed back to the posterior branch of the second cervical before that nerve gave off the filament to the obliquus inferior.

The inferior oblique muscle was then found, passing from the tip of the transverse process of the atlas to the spinous process of the axis; also the superior oblique and the rectus capitis posticus major, the three bounding the suboccipital triangle, in which was discovered the suboccipital nerve lying in close relation with the vertebral artery. The nerve was followed back to its exit from the spinal canal, between the occipital bone and the posterior arch of the atlas.

Following down beneath the complexus, the external branch of the posterior division of the third cervical was found. This was followed back to the bifurcation of the main trunk. One had at command, then, the nerve supply to the inferior oblique, the rectus capitis posticus major, and the splenius, the three posterior rotators, the first being supplied by the first and second cervical, the rectus by the suboccipital from the first cervical, and the splenius by the second and third cervical.

Each nerve was followed well back to the spine and a half to three quarters of an inch excised from each of the three. Buried muscular sutures were inserted, a drainage-tube laid to the bottom of the wound, and the skin sewed up. A large anti-septic dressing was applied and the head fixed in moderate extension by plaster. The operation consumed nearly two hours, the dissection being necessarily carried on slowly and carefully. I have already said that the patient's neck was very short and thick. The deeper muscles seemed enlarged and dense. The wound was deep, yet the length of the incision gave access to its bottom, and the light from a window was amply sufficient to enable one to see clearly. The recognition of the occipitalis major, running as it does in the direction of the fibers of the complexus aponeurosis, was not easy. It was only after following out several strands of fascia that I found the nerve. The suboccipital lay deep, yet was found far more easily than the third nerve, which was beneath the lower part of the complexus. The hæmorrhage was slight, yet oozing was at times troublesome. The abdominal position of the patient made the administration of the anæsthetic difficult, yet his condition remained at all times good.

On coming out of the anæsthetic the patient had no spasms of the neck; the head was in the median line, and remained

\* Read by invitation before the New York Neurological Society, December 1, 1891.

† *Annals of Surgery*, January, 1891. The procedure followed by me is, in the main, that advised by Keen.

\* For this opportunity I am indebted to Dr. L. W. Hotchkiss, Assistant Demonstrator of Anatomy at the College of Physicians and Surgeons, who kindly assisted at the operation.

there until the final removal of the dressings. The wound healed *per primam* throughout, the tube was removed on the fifth day, and all dressings were taken off at the end of ten days. At this time there were a few slight spasms, but they did not persist. Directions were given regarding massage and the like, but they were disregarded, and the head gradually assumed a position of contraction, with the face drawn to the right.

The patient escaped from observation and was not seen until during the past month, when he was examined by Dr. Amidon and myself, and, at our request, by Dr. C. L. Dana. The present condition is as follows: When the patient stands erect, the right acromion is on a plane an inch and a half to two inches above the left. The head is carried in a position of rotation to the right, and lateral inclination a little downward to the same side. Voluntary rotation to the right is normal, and when the head is in this position it can, with effort, be returned to the median line by the right sterno-mastoid; but effort to carry it beyond this and to the left is attended with difficulty, and seems antagonized by deeper muscles of the right side. Extension of the head is very nearly normal, and, when it is thus extended, rotation to either side is free and unrestrained. Flexion of the head on the chest is nearly normal, but when in position of flexion, rotation to the left is most difficult. The head can be drawn toward the shoulders more freely on the right side than on the left. There seems to be a tonic spasm of the anterior fibers of the right trapezius, and a hard, tense cord can be felt between the trapezius and sterno-mastoid; this is apparently the levator anguli scapulae. There is a scoliosis of the cervical vertebrae, the convexity of this being to the left, above. There is a skin "fold" where it laps over on the right side of the neck, and beneath this fold lies the cicatrix, the line of which is hardly noticeable. There is a fairly marked depression at the site of the outer third of the cicatrix.

From the fact that rotation is free when the head is extended, it seems probable that there is a tonic spasm or permanent shortening in the splenius. The patient has no pain or spasmodic movements, and, in spite of his present contracted wryneck, he expresses himself as feeling that his condition is vastly better than it was before the operation.\*

As stated in the foregoing, the operation for systematic division of the nerves supplying the posterior rotators was first formulated by Keen, who, in addition to his painstaking work upon the cadaver, has had a single opportunity to carry out the procedure upon a living subject.

His patient was a woman, fifty-four years of age, who first came under the observation of Dr. Francis X. Dercum,† March 27, 1886. She then stated that for two years past she had suffered from involuntary rotation of the head toward the left shoulder. The movement frequently recurred during conversation. The chin turned toward the left, and was slightly elevated. She had distinct hypertrophy of the sterno-cleido-mastoid muscle upon the right side. There was some diffuse pain at the back of the neck, though it could not be determined that this was related to the spasm. She was operated upon, June 27, 1888, by Dr. Ashhurst, who removed four inches of the spinal accessory nerve, both branches being embraced in the operation and extreme traction being made upon the trunk. Following the operation the spasms disappeared for a week, but then returned and were apparently unchanged, the frequency being about the same as

\* The condition now, February 24, 1892, is vastly improved; the deformity is but slight, all movements of the head are quite free, there has been no return of the spasms, and he is able to attend to his daily work, which was impossible before the operation.

† *Journal of Nervous and Mental Disease*, 1890, p. 830.

before. Some time afterward she was subjected to operation by Dr. Keen, practically in the manner indicated in the case which I have narrated.

The spasms ceased immediately after the operation, but returned at the end of a week, less violently, however, than before. The rotation was not so marked, and the patient could steady the head with the hand, this being impossible before the operation.

Dr. Keen saw the patient a year later, and thought the posterior muscles free from implication, with the exception of the splenius, some nerves of which had perhaps escaped division. The patient's condition was, however, markedly improved.

I am able to find but one other reported case in which the posterior cervical nerves have been excised. This is reported by Mr. Noble Smith (*British Medical Journal*, 1891, i, p. 752).\* His patient was a lady of forty-one years, who had suffered for sixteen years with severe spasmodic wryneck, which commenced a few weeks after a severe strain.

When the patient was first seen (October 30, 1889) the head was bent laterally toward the right, so that the cervical part of the spine was curved very severely to the left. There was constant and very violent spasmodic action of the left sterno-mastoid and upper part of the left trapezius muscles, drawing the face toward the right shoulder. There was also spasmodic action in the splenius capitis and other muscles on the right side of the neck, these producing the same inclination of the head as the muscles of the opposite side already named. For four months fixation and medicinal remedies were tried. The effect of a supporting instrument was decidedly beneficial, but it only partly controlled the spasmodic action. It was then proposed to stretch the spinal accessory nerve.

On March 6, 1890, this nerve was firmly stretched, the immediate result of which operation was decidedly favorable, but soon began to wear off, and it became evident in about a week that further measures were necessary. Excision of a part of the nerve was then determined upon.

On April 22d a piece of the spinal accessory nerve, a third of an inch long, was excised. The result of this operation was complete paralysis of the sterno-mastoid and trapezius, and a feeling of immense relief to the patient, as the spasms were very greatly lessened. She was up and about in a week after the operation, and could turn the head easily to the left side and control it in that position; she could hold it for a short time in any position she liked, but the spasms on the right side continued, the splenius capitis being the greatest offender. After waiting a few weeks and finding that there was no further improvement, it was determined to operate upon the posterior branches of the cervical nerves upon the right side. On May 28, 1890, an incision was made from the occiput downward for about three inches, parallel to and about an inch to the right of the spinous processes, through the trapezius down to the edge of the splenius, some of the fibers of which muscle were subsequently divided to enlarge the wound; then through the complexus, eventually exposing the posterior branches of the cervical nerves.† The great occipital nerve then came into view. This was separated from its attachments, drawn aside, and a piece of its external branch, as well as of the third and fourth posterior branches, were excised. The splenius was separated from the parts beneath it, and nerve filaments passing

\* Smith seems to have made his observations without knowledge of the previous work done by Keen.

† The author does not enumerate the individual nerves.

into it were carefully excised. The same procedure was adopted with the complexus. The suboccipital nerve was left intact, as the dissection was a rather deep one and veins interfered. Recovery from the operation was complete, the spasms ceased, and at the time of report, eleven months after operation, had not returned. The loss of power was very slight, and the patient expressed freedom from discomfort or disability.

We have, then, three cases in which these posterior cervical nerves have been resected. In Keen's case there was amelioration, though not complete cessation, of the spasms. In my own the spasmodic action was stopped, yet the patient now presents a moderate degree of tonic wryneck, while in Noble Smith's the cure seems to have been a complete one. I can but think that Smith was cautious in resecting the fourth nerve and in cutting out all filaments to the splenius and complexus, and in another case I should be inclined to follow this procedure. I am hardly prepared to express a positive opinion as to just what muscles are now affected in the patient whom you have seen to-night. There seems no reason for believing that those of the left side are in any way involved. The muscles which rotate the head to the side on which they themselves are situated are the inferior oblique, rectus capitis lateralis, rectus capitis posterior major and minor, trachelo-mastoid, and splenius. It seems quite probable that more than one of these are affected. There is no tonic extension of the head, yet when the head is in extension, rotation is free.

If flexion with rotation to the left were difficult, we could feel assured that the muscles which both extend and rotate to the right were at fault, and that superextension, relaxing those muscles, would allow the other rotators to effect the turn to the opposite side. Again, if only the simple rotators were implicated, there seems no reason why rotation should be freer with the head in full extension. The patient carries the head somewhat inclined to the right side. This inclination, with rotation to the same side, could be effected by the trachelo-mastoid and splenius, especially the anterior fibers of the latter muscle, and I think that we may assume that extension of the head would tend to relax the splenius and thus permit of more easy rotation. These muscles are supplied by the external branch of the second cervical, which nerve was resected at its exit from the intervertebral foramen, yet it is quite possible that they receive additional fibers from lower nerves. It is also possible that filaments were given off from the nerves before their section. As I have said, however, I can only conjecture as to which of the deeper muscles are now affected.

With a view to comparing the relative advantages of the transverse and longitudinal incisions, I have very recently made further dissection of the parts on the cadaver. Each procedure—the transverse cut of Keen, and the longitudinal one of Smith—seems to possess advantages. In each the incision must be a liberal one. Keen's transverse division of the trapezius and complexus gives better command of the suboccipital triangle. It is not as easy in this, however, to gain access to the third and fourth nerves as when the cut is longitudinal. Keen did not divide the fourth nerve, yet, as I have said, I think that I should do this in an-

other case. When the patient is fat, either incision must be a deep one. In one subject which I dissected, the first, third, and fourth nerves were exceedingly small, and only found with much difficulty after long and careful dissection.

I am at present inclined to think that if the patient presented a long, thin neck, I should make the longitudinal incision, and that I should employ the transverse cut of Keen in those people whose necks are short and thick.

It is needless to say that good light and ample retraction are indispensable. The less of fat the region presents, the easier will it be to recognize the parts, yet I should feel that it would always be best to advise the patient, before operation, of the possibilities of failure. Certainly it is an operation which I should hesitate to undertake without having first become familiar with the region by dissection of the dead subject.

In my own case the divided muscles were sutured and seem to have suffered nothing as a consequence of their mutilation.

Hæmorrhage is not an important factor in the operation. Oozing of blood from the divided muscles bothers one by obscuring the field of work and delays one in point of time, yet there is little danger of wounding large vessels. The vertebral artery and vein may come into view in the suboccipital triangle, and it is needless to say that they are to be carefully avoided, for they lie very deep and it might be most difficult to ligate them.

Appropriate after-treatment by confinement of the head, massage, and the like should receive careful attention.

Regarding the indications for operation in spasmodic wryneck, I need not speak before this society. It is to be resorted to when other measures fail. Drugs, gelsemium, hyoscyamine, and other antispasmodics, atropine injections, massage, position, electricity, and other means will cure a certain number of cases, but will leave a certain number uncured, and these last must be subjected to surgical procedure. We have seen that in operations upon these posterior nerves we have few data to guide us. In affections of the anterior muscles, however, those supplied by the spinal accessory nerve, we have the experience of many observers. Here various procedures have been adopted—myotomy, nerve ligature, elongation of the nerve, division, and resection. Of these, the last—the resection of a considerable portion of the nerve, possibly combined with firm stretching of the proximal fragment—enjoys the best repute; and while consideration of the operations upon this accessory nerve is without the scope of this paper, it may not be out of place to briefly refer to the investigations of a recent French surgeon, Petit, who, in July of this year, published (*Traitement du torticollis spasmodique par la résection du nerf spinal*, *L'Union médicale*, July 9, 1891) the results in twenty-six cases in which the spinal accessory nerve had been resected for spasmodic torticollis. Of these twenty-six cases, thirteen were cured, in seven the amelioration was marked, in two the improvement was less marked, in three it was temporary, and in one case death resulted from phlegmonous erysipelas.\*

\* It is needless to say that under present operative methods septic processes play a very small rôle.

Petit says: "Thus, of twenty-six patients, twenty have been either completely cured, or so ameliorated that they have been able to resume their occupations. This certainly justifies those surgeons who have practiced resection of nerves in the treatment of spasmodic wryneck."

It is to be regretted that the author does not state the length of time after operation which had elapsed when the term "cure" was applied.

I have purposely refrained from speaking of the occurrence of spasmodic wryneck, of its causes, pathology, or medical or mechanical treatment, and in conclusion beg to lay before you this proposition: That in spasmodic affection of muscles supplied by the posterior branches of the upper cervical nerves resection of those nerves is a procedure, practically devoid of danger, which offers many chances for marked anchioration and a fair prospect of permanent cure.

NOTES ON  
TUBERCULOSIS OF THE URINARY BLADDER,  
AND THE VALUE OF SUPRAPUBIC CYSTOTOMY  
IN ITS TREATMENT.\*

BY LEWIS S. PILCHER, M. D.,  
BROOKLYN.

OBSERVATIONS bearing upon tuberculosis of the urinary bladder have not yet attained so great a number as to make the report of individual cases unimportant, unimportant, or uninteresting. The suffering which the disease entails, its intractable nature, and the difficulties which sometimes attend the diagnosis, constitute conditions that will always command the earnest attention of surgeons.

It is possible that hereafter tubercular infection may be demonstrated to be a more frequent cause of intractable cystitis than has up to the present time been recognized. Certainly the results of the bacteriological studies of Rovsing are very suggestive in this direction. This observer is reported (*Ann. of the Univ. Med. Sci.*, 1891, vol. i, L, p. 40) to have detected tubercle bacilli in the bladder discharges in three out of thirty cases of cystitis subjected to examination by him.

Cases of cystitis which develop in the course of the progress of recognized tubercular disease of other portions of the genito-urinary tract are not likely to fail of immediate classification as being manifestations of an extending tuberculosis, without special stress having been laid upon the identification in the bladder discharges of the specific micro-organism. But in the more obscure cases, where the primary lesion is in the bladder wall itself, or, if this is consecutive, the primary deposit elsewhere in the genito-urinary tract has eluded identification, the importance of bacteriological methods for establishing a diagnosis, and with the diagnosis a prognosis and therapy, is beyond question. In the investigation of a tuberculous bladder the sound can convey but little positive information; the cystoscopy—if, by rare chance, when it is introduced, the fluid

contents of the bladder are clear enough to enable its mirrors to reflect any portion of the bladder wall—can reveal but imperfectly and uncertainly the degenerative and inflammatory changes that may be present, while direct ocular inspection and palpation with the finger-tip through a dilated suprapubic opening still need the confirmation of the bacteriological test in order to establish beyond question the opinions which they may have suggested.

The application of this test, however, in the early stage of a primary bladder tuberculosis may be so impracticable as to make it unavailable in establishing the diagnosis; a certain amount of breaking down of tissue and of discharge of infected *débris* into the interior of the bladder is necessary before the bladder discharges can possibly respond to the tests that may be applied, so that, for a time at least, all precise diagnostic measures may remain at fault.

In illustration of this possible difficulty of making a positive diagnosis in the early history of a case, I cite the following case, although it is still incomplete, but does not on that account any the less illustrate the point in question:

CASE I.—Alexander M., an active young man of twenty-two years. In good health until development of present trouble. One sister died of carcinoma of the breast at thirty-four years of age; a second sister died at thirty years, of some bladder disease, after an illness of four years; a third sister, younger than himself, is the subject of tuberculosis of the cervical glands. His parents are healthy, except a tendency to rheumatism on the part of the father. Six months before coming under observation the patient was troubled for a period of two weeks by frequency of micturition. No pain and no change in quality of urine noticed. This subsided spontaneously and did not recur for a period of four months, when it again developed, and the occasional escape of fibrinous, shreddy material in the urine was noticed. This again subsided for a brief period, until, after a prolonged ride upon his bicycle, he was attacked with hæmaturia, with acute cystic irritation, which had persisted with steady aggravation, despite intelligent treatment, for two weeks or more, when I first saw him. At that time he was urinating every hour, or at less intervals, with pain and tenesmus; the urine constantly contained much blood and abundant bladder epithelium and leucocytes. Some flakes of somewhat consistent material, apparently of organized tissue, were also present in the urine. Examination of the bladder with a sound gave negative results; the use of the cystoscope was impracticable, owing to the constant hæmorrhage; the rectal touch was negative. The shreddy material, having been submitted to a pathologist for examination, was reported to be fibrillated connective tissue inclosing cell elements, and to be suggestive of the existence of papilloma of the bladder. The indications for suprapubic cystotomy being thus well established, the patient was removed to the Methodist Hospital, where the operation was duly performed. The opening of the bladder and inspection of its interior did not reveal the hoped-for limited papilloma, but instead thereof, on the right lateral wall of the bladder, extending upward from the base, an area of the mucous membrane as large as a silver dollar, intensely congested, velvety in appearance, raised somewhat above the surface of the surrounding normal mucous membrane, as if by infiltration of the submucous tissue, and bleeding freely when touched. In view of the age and history of the patient, the most probable opinion that these conditions suggested was that the lesion was of a tuberculous nature. This diagnosis, however, needs confirmation. Repeated examinations of the urinary

\* Read before the New York Surgical Society, December 9, 1891.

sediment made since the operation have thus far failed to detect the presence of the bacilli of tuberculosis in it. Inoculation experiments are under way, but it is still too early to obtain any report therefrom.

Meanwhile the treatment pursued was moderate curetting of the diseased surface; immediate tamponade of the bladder with iodoform gauze for twenty-four hours; subsequent daily irrigations through the suprapubic wound, first with boro-salicylic solutions, and later with solutions of nitrate of silver (two grains to one fluidounce). A steady improvement in both the local and general condition of the patient has resulted; pain has vanished, blood has nearly disappeared from the urine, he sleeps well, eats with appetite, and has gained in weight.\*

Another case (also now under observation in my service in the same hospital as a patient of my assistant, Dr. Bogart) will bear citation here in further illustration of the same point.

CASE II.—John W. F., an athletic young man, twenty-eight years of age, is admitted for relief of fistulæ in ano with the following history: Several of his father's brothers had died of pulmonary tuberculosis. He himself had never had any venereal disease. Eight years previously to admission, when in otherwise perfect physical health, he began to experience frequent and straining micturition. Never any blood. After eighteen months the symptoms became more aggravated, the pain keener, and a slight urethral discharge was noted. The external meatus was slit up without relief. Every few months an acute attack, apparently due to increased prostatic congestion, with increase of pain and of discharge, would occur. Violent exercise and constipation were the exciting causes of these attacks. By watchfulness in these respects he finally learned to prevent these recurrent acute attacks, but the urethral discharge persisted. The testicles are free from disease. Two years ago an eminent genito-urinary surgeon of Boston, under whose care he was at that time, detected enlargement and induration of one of the seminal vesicles. Bacteriological examination of the semen and of the urine failed to show any bacilli of tuberculosis. The cystoscope was used without any definite findings. Meanwhile, about a year before coming under my own observation, the presence of pus in the ischio-rectal space was detected, which after some months was evacuated, leaving two persistent fistulous tracts, one of which communicates with the bowel.

With the evacuation of this abscess the bladder symptoms have become less urgent, but a sense of discomfort in that viscus, and the need of care to prevent its becoming aggravated, is rarely absent.

The case well illustrates the difficulties which attend the coming to a positive diagnosis in a case of primary tuberculosis of the bladder. Even at this late date, though there is but little room for doubt as to the tubercular nature of the prostatic and cystic symptoms that have so many years tortured this patient, it can not be said to be settled beyond possible dispute.

Thus much with reference to this point of diagnosis. The special object of this communication was, however, to report the effects which had resulted from the performance of suprapubic cystotomy in a limited number of cases of tubercular disease of the bladder that have been recently under my care. My attention was called to the possible benefits of this procedure by the paper which Guyon, of

\* The patient has now, three months since this was written, apparently become perfectly well.

Paris, read before the French Surgical Congress in 1889, in which he reported three cases of the kind; two of them were followed by marked relief to the bladder symptoms, death occurring one and two years, respectively, later from renal degeneration. The third patient, a male of twenty-four years of age, who had been suffering for two years with symptoms, made an apparently complete recovery, remaining well four years after the operation, having gained in flesh and strength. Other cases nearly as favorable have also been reported by other surgeons, but I have made no effort to collect them.

My first case is as follows:

CASE III.—Frank B., an active young man, eighteen years of age, was admitted to the Methodist Episcopal Hospital in September, 1889, for relief of hæmaturia and irritable bladder. The symptoms dated back for two years, during which he had suffered from unduly frequent micturition, with occasional hæmaturia. The hæmaturia had been constant for the three weeks previous to admission. Micturition is painful, especially when much blood is to be voided. Has frequent temporary retention of urine by blocking up of urethra by clots. Has enlargement of both epididymides, with consolidation at apex of left lung. Explorations of bladder by sounds and cystoscope, negative. Irrigations of bladder with boric acid and hydrastis canadensis for two weeks without advantage to patient. Patient suffers much from occasional blocking of urethra by masses composed of fibrin and phosphatic concretions. Suprapubic cystotomy. After the bladder had been opened and its base fully exposed, there came into view an eroded ulcer, about an inch in diameter, with overhanging edges. Considerable sabulous matter and mucopus was removed from the bladder, the ulcer curetted, and the cavity of the bladder filled with iodoform gauze. Median perineal section with introduction of hard-rubber drainage-tube to base of bladder. This tube, after a few days, was found to be a source of irritation and was removed, the suprapubic opening alone being depended upon for drainage. Systematic antiseptic irrigations of bladder. Gradual improvement in condition of patient. Steady contraction of suprapubic wound. At the end of a month suprapubic wound nearly closed. Begins to urinate *per urethram*. During succeeding months gradual increase in proportion of urine passed *per urethram*. At the end of the third month only a very small amount of urine escapes through the suprapubic opening when bladder becomes overdistended from failure to empty the bladder during sleep. Patient retains his urine from one to two hours during the day, and twice that time at night, urinating easier and without pain. General health greatly improved. Discharged. After leaving hospital, a steady improvement. This continued, and, at the end of a year from his entrance to hospital, patient returned to college, his general health being excellent. Between 6 A. M. and 10 P. M. he urinates about ten times without pain, but during the night only twice. There is at irregular intervals an occasional escape of urine through the suprapubic fistula.

Upon recent examination of this patient, two years after the operation, I find him in apparent robust health. He is pursuing his college studies, and is especially interested in college athletics. Has gained much in weight; the epididymal deposits remain *in statu quo*; the suprapubic opening is firmly closed, no urine having escaped through it for more than a year. He rises twice during the night to relieve his bladder, and during the day time urinates at intervals of about two hours.

CASE IV.—Nellie J., aged nineteen years, was admitted into the Methodist Episcopal Hospital in August, 1890, for the

relief of chronic cystitis. For two years she had been troubled by frequent and painful micturition, with occasional appearance of blood-clots in the urine. When admitted she was compelled to urinate every hour, the act being attended with a varying amount of pain. The urine contained abundant pus. The general health was fairly good.

Bacteriological examination of the urinary deposits revealed the presence in them of the bacilli of tuberculosis. After a four weeks' trial of the common remedies for cystitis, without improvement, September 5, 1890, she was subjected to suprapubic cystotomy by my assistant, Dr. Bogart. This revealed the presence at the base of the bladder, extending upon its left lateral wall, of a large ulcerated surface, with very friable and easily bleeding granulations. The bladder was cleansed by irrigation and filled with iodoform gauze. At the end of a week, for the iodoform gauze dressings daily irrigations with solution of carbolic acid were substituted. At the end of four weeks the urine, as it escapes from the suprapubic opening, is quite clear. Her general condition, however, is not so good, and physical examination of the chest reveals some deposit in both apices.

A week later considerable pus is again found mixed with the urine, and irrigations are painful. Irrigations are suspended, and balsam of Peru and cocaine are instilled into the bladder daily for a time. Finally, however, all intravesical applications are suspended. For some weeks her condition varied, but a gradual improvement in strength and appetite finally became established, and at the end of five months and a half after the operation, having regained ability to resume dress and to walk about, she was discharged from the hospital February 20, 1891. She still had at times much pain in the bladder, her urine still contained pus, and escaped entirely through the suprapubic sinus. During the year following her return home her bladder condition remained unchanged. She was able to be about and do some housework. The pulmonary tuberculosis, however, continued to develop, and finally determined her death in the fifteenth month after the cystotomy had been done.

CASE V.—In June, 1890, Joseph S., some fifty years of age, was brought to me by his physician, Dr. W. E. Beardsley, for examination. The case was simple and clear in its character. Beginning five years before with fistula in ano, he had successively developed tuberculosis of the larynx, of the lungs, of both epididymides, of the prostate, seminal vesicles, and base of the bladder. Micturition was frequent and painful, but the suffering was not so pronounced as to make a cystotomy seem advisable at the time, especially in view of his generalized tuberculosis. During the ensuing summer, however, the bladder symptoms increased in severity to such a degree that cystotomy became more urgently indicated. The suprapubic section was accordingly done in New York city in October, Dr. E. L. Keyes being the operator. Examination of the interior of the bladder failed to reveal any ulcer or special characteristic appearance of tuberculosis other than a diffuse, intense congestion of the mucosa at the base of the bladder, with many minute granular elevations dotting the surface. Intravesical iodoformized applications were made and suprapubic drainage provided for. After about three weeks, having been brought back to his home in Brooklyn, he again came under my care. But little relief had been secured by the suprapubic section; much constant pain in the bladder demanded frequent administration of morphine for its control; a total lack of reparative power manifested itself in the operative wound; and every effort to promote repair—involving general hygiene, supporting and stimulating treatment, and local stimulants—was fruitless to provoke any tendency to cicatrization or to prevent undermining of the adjacent connective-tissue planes. He gradually sank,

and died by exhaustion ten weeks after the cystotomy was done.

*Remarks.*—Of the four cases now detailed in which suprapubic cystotomy was resorted to, in two of them very marked benefit has resulted from the procedure. In the other two no benefit, but, on the whole, decided disadvantage, I think, was the result.

In the case of the girl the opening of the bladder above the pubes was a very satisfactory proceeding, as an aid to the exploration of the bladder and in the help which it gave us in ascertaining its precise condition, but its after-care required prolonged confinement to the bed; and the discomforts attending the constant outflow of the urine above the pubes could only partially be overcome by the use of voluminous absorbent pads. I doubt whether any benefit was derived from the efforts at topical medication that were made; indeed, I question whether in any of these cases any substantial advantage is to be hoped for by attempts at special topical antitubercular treatment. The tubercular infiltration is not a superficial infection, to be arrested or diminished by the powderings, instillations, or irrigations that are available for use in the interior of the bladder. The curette and the cautery can not be resorted to with any such degree of thoroughness as to encourage a hope that even a considerable portion of presumably infected tissue has been removed by them. The most that can be hoped for from treatment is to prevent the collection of urine in the bladder, to keep the bladder at rest, and to mollify the effects of the existing infection by relieving pain, removing *débris* and irritating secretions, preventing muscular spasm, and restraining inflammation. If this can be accomplished, it may possibly be that in certain very favorable cases an indefinite arrest, even the entire recession, of the tuberculosis may take place.

The value of the suprapubic incision, therefore, does not consist so much in any opportunity which it may afford to give access to the disease itself, but rather in the superior degree in which it facilitates the accomplishment of these apparently secondary indications named.

In the male I think there can be no question as to the superiority of a suprapubic opening to a perineal one in carrying on the treatment of this special class of cases. In the female, however, the relations of the base of the bladder to the vagina are such as to suggest that by the formation of a generous vesico-vaginal opening an equally efficient and much more convenient outlet to the bladder would be furnished than could be had above the pubes. My experience in the case of the girl in question would suggest to me that in a similar case again it would be better, after having made the exploration of the bladder by the suprapubic opening, to establish a free opening through its base into the vagina and then suture the suprapubic wound, relying on the vaginal outlet for the after-treatment of the case.

Perineal drainage was tried by me as an accessory in one man (Case III), but the pain and irritation caused by the presence of the tube in that location, its vesical end necessarily resting upon the ulcerated surface, made its withdrawal necessary after a very short time. Further experience and observation have satisfied me that it can rarely be of any

added advantage to have a perineal opening as long as the suprapubic opening remains patent and the contractility of the bladder walls has not been destroyed.

A device to facilitate drainage and intravesical irrigations which I have employed in my latest case has worked so well and given so much comfort that I will mention it. It consists simply of the use of two soft-rubber tubes—large caliber drainage-tubes, 5 to 7 mm. interior diameter—introduced side by side through the suprapubic opening, projecting unequally into the bladder, one being carried into the bladder a sufficient distance to nearly reach its base, the other being only long enough to fairly reach the cavity of the bladder. Neither of these should have any lateral openings. Ready drainage is thus secured both from the bottom and the top of the bladder, and by alternately sending an irrigating current, first through one and then through the other of the tubes, very thorough and painless washing out of the organ can be readily done. Both of these tubes I cut off flush with the surface of the skin. By covering their orifices with a somewhat voluminous absorbent dressing—bags of sawdust are used by myself—which is replaced as often as it becomes saturated with urine, the patient is kept dry and comparatively comfortable.

Two practical questions suggest themselves in connection with this subject to which, in conclusion, some consideration may be given—viz.:

1. How early in a case of possible bladder tuberculosis is a suprapubic section desirable?
2. How long is it desirable to maintain the suprapubic opening patent?

The answer to the first of these questions, I take it, is to be found in a consideration of the indications which the operation may be accepted as subserving. I have already expressed my conviction that it is by securing bladder rest and drainage that the operation is especially useful. The symptoms that demand attention are those usually of cystitis; if these symptoms—it is unnecessary to recount them or analyze them here—if, I say, these symptoms do not readily yield to the well-known accepted constitutional and local measures of treatment, recourse to cystotomy is indicated and should not be unduly deferred while the general strength is being sapped by the local suffering, the extension of disease, and the absorption of deleterious substances into the circulation.

The second question must also receive an indefinite answer. Case III of the series reported this evening shows that in the most favorably affected cases a gradual subsidence of the symptoms which had called for operation may take place; the ulcers cicatrize, the inflamed mucosa resumes its normal state, the urine becomes bland and healthy, or at least comparatively unirritating, and the bladder becomes again capable of acting as a reservoir for urine, and of painlessly expelling it at suitable intervals.

When this condition has been secured, the suprapubic opening may be allowed to close, but a prolonged period of time, possibly many months, must be expected to be required to bring about this end.

In other cases it is to be expected that comparative comfort only will be enjoyed as long as the bladder is not called

upon to retain the urine for any time, which will necessitate the indefinite retention of the suprapubic opening and a suitable permanent drainage apparatus.

In much the larger proportion of cases, however, and especially those in which the bladder disease is secondary to or associated with progressive renal or pulmonary tuberculosis, it must be that the fatal termination of the case will early dispose of any question that might have arisen as to the permanency of the suprapubic opening, which may have been made for the purpose of temporarily alleviating the suffering caused by the condition of the bladder.

## ESSENTIALS IN OPHTHALMOLOGY FOR THE GENERAL PRACTITIONER.\*

BY L. A. W. ALLEMAN, M. A., M. D.,

BROOKLYN, N. Y.

It is with the greatest possible satisfaction that the physician of to-day recognizes that medicine has at length become a science—not, it is true, an exact science, but a pre-eminently progressive one. The few fundamental branches which once constituted the requirements of a medical education have now put forth many vigorous offshoots. It is no longer possible for the conscientious medical student to master in the time usually devoted to preparatory study all that is to-day known of medicine, and then to hold fast to that which is good, but in the very outset of his education he must exercise his selective faculty, and too often, later on, he regrets that he was not better advised as to the most profitable use he could make of his time.

We are all of us frequently called upon to give such advice to medical students and to those recent graduates to whom an unappreciative public allows abundant leisure, which they wish to devote to rounding out their medical education. Since this question arises nowhere more frequently than in connection with the study of diseases of the eye, I have thought it of interest to ask you to discuss with me what knowledge of this special branch is essential to a general medical education.

To the medical student the study of ophthalmology centers in the ophthalmoscope. It is the "outward and visible sign," the pre-eminent weapon of the oculist. The first flickering flame of enthusiasm for eye work in the breast of the student provokes the inquiries, "Shall I get an ophthalmoscope?" "How much does the instrument cost?" "Which one is best adapted for student's work?" and so on. I always advise against its purchase, unless the man intends to follow eye work after graduation, and no doubt often seem most inconsistent. After pointing out the advantage in many medical cases of an examination of the eye ground, it is a natural inference that the well-equipped general practitioner should be able to avail himself of its aid, but I am more and more convinced that the advice is sound, and I doubt not that I could put in evi-

\* Read before the Kings County Medical Association, November 10, 1891.

dence the experience of many of the gentlemen present, who, in moments of enthusiasm, have invested in such instruments.

That the ophthalmoscope is not a valuable aid to diagnosis in the hands of the average medical man is not because the data which it gives are valueless, but because the instrument is only of value to the man who has sufficient opportunity for its employment to keep himself expert in its use.

In the first place, it requires some practice to see the fundus oculi at all; having mastered this, one must get a standard of normal. Then there are in health wide variations in the appearance of the fundus, and some of these so closely simulate diseased conditions that unless the points of differential diagnosis between pathological conditions and physiological variations are most thoroughly impressed by long practice, they are a very annoying stumbling-block.

Having once gained sufficient experience in the use of the instrument to profit by its showings, its use can not be long neglected without serious loss of expertness, and just here is where our general men find the difficulty. In the busy rounds of professional work cases requiring its use are not very frequent, and time does not permit recourse to the clinic to keep in practice. The cases in which an ophthalmoscopic examination is valuable as an aid to diagnosis are among the most difficult we encounter, and the physician with a fair working knowledge of the instrument finds that he falls just short of that absolute confidence in his findings which is essential to his purpose.

A much less ambitious instrument than the ophthalmoscope, and one with the use of which every student should familiarize himself, is a simple mirror. It is, in fact, an ophthalmoscope, save that it lacks the lenses, which are usually placed behind the mirror. This instrument takes the place of the more elaborate one for nearly every purpose save the estimation of refraction. With a very little practice one can learn to illuminate the interior of the eye and obtain a red reflex through the pupil. This will give much valuable information. For example, opacities in the lens can be seen, and a diagnosis of beginning cataract made, its progress can be watched, and by this simple procedure many a patient in some remote district would be saved a disheartening journey to the city for the purpose of undergoing an operation for a cataract which either does not exist or is not sufficiently mature for operation. By its employment irregularities of the pupil found in iritis can be seen, floating vitreous opacities recognized, and, in the hands of one sufficiently skilled, a fair idea of the condition of the fundus gained.

As to the diseases of the eye recognizable by the ophthalmoscope and due to some constitutional disorder, such as Bright's disease, diabetes, and the like, it suffices to point out that such diseases exist, and that, in these cases, an examination of the fundus oculi is sometimes invaluable as an aid to diagnosis.

The inspection of the eye to determine the presence of a foreign body is an important matter—a task frequently imposed on the general practitioner. A man suffering from a cinder, for example, which is rasping up the delicate mem-

brane, is not always and altogether reasonable. At any other time he might admit that his case was one which should properly be sent to a specialist, but if compelled to wait over night to see one, the patient may not be altogether charitable in his opinion of the doctor who declines to relieve him of his suffering. It is therefore well for every one to cultivate what knowledge he can of the removal of foreign bodies, when they are simply lodged in the conjunctival sac or cornea, and have not penetrated the eye. Here no amount of telling will do for the student what a little showing will, nor can it give him manual dexterity, but he should be advised that if he begins his examination of an eye irritated by the presence of a foreign body by the instillation of a drop of a four per-cent. solution of hydrochloride of cocaine the matter will be much simplified; also warn him in endeavoring to open the lids to examine the eye, not to dig the fingers into the eye, making pressure upon the sensitive globe, thus exciting spasm of the lids and increasing the difficulty of examination; but, resting one thumb against the margin of the orbital cavity and the other upon the malar bone, to make firm traction. In this way the eye is much more easily opened. A condensing lens of some sort can usually be obtained, and by it a ray of artificial light focused upon the eye. A very little practice enables one to evert the lid, and in ordinary cases no difficulty is experienced in removing the foreign body. When it is deeply imbedded in the cornea, much caution is required to avoid adding to the mischief already done by rough manipulation in its removal. These points are so self-evident as to scarcely require comment.

As to the diseases of the eye against which the student should be repeatedly warned, I think the one of chiefest importance is ophthalmia neonatorum. So terrible are the effects of this disease and so simple a matter is its prevention, and in the beginning its cure when properly managed, that I feel that we should preach upon its dangers in season and out of season. When we reflect that nearly a fourth part of the inmates of blind asylums are victims of this disease, when we consider the life-long misery which blindness entails, we must feel that a heavy weight of responsibility rests upon the man who fails to impress upon those he presumes to instruct the dangers of this terrible disease and the precautions necessary for its prevention. Not only does the prevention of blindness demand our consideration from sympathy for these unfortunate victims, which, in all conscience, is imperative enough, but it is our duty as citizens to try and relieve the State of a burden which I regret to say is an increasing one. Most of the blind are not only a loss to society by being withdrawn from the body of wealth-makers, but are a direct tax upon the industry of others; in this State alone the loss to the community from the blind population was estimated by Dr. Lucien Howe, who deserves great credit for arousing interest in this subject, at twenty-five million dollars in 1887, and would no doubt be found still greater at the present time. It is not possible here to enter further into the discussion of the prevention of this disease, but suffice it to say that every student, every midwife, every nurse, any one, in fact, who may at any time come into contact with new-born children, should

be taught that the dropping into the eye of the child, immediately after birth, of a drop of a two-per-cent. solution of nitrate of silver gives practical immunity from the disease, and that finding a case already developed, the law requires the notification of some responsible officer. The law reads:

CHAP. XLI.—*An Act for the Prevention of Blindness.*

SECTION 1. Should any midwife or nurse having charge of an infant in this State, notice that one or both eyes of such infant are inflamed or reddened at any time within two weeks after its birth, it shall be the duty of such midwife or nurse so having charge of such infant, to report the fact in writing, within six hours, to the health officer or some legally qualified practitioner of medicine, of the city, town, or district in which the parents of the infant reside.

SEC. 2. Any failure to comply with the provisions of this act shall be punishable by a fine not to exceed one hundred dollars, or imprisonment not to exceed six months, or both.

SEC. 3. This act shall take effect on the first of September, eighteen hundred and ninety.

When it is impossible to place the case in other hands, one can easily refer to the text-books for treatment, which consists of antiseptic washes, iced compresses, nitrate of silver, and the like, which I can not here describe in detail. A disease of similar nature and one which no physician can ever afford to disregard, alike for his own safety and that of his patient, is gonorrhœal ophthalmia.

When an eye is inoculated with gonorrhœal pus, an inflammation of frightful intensity follows. In some instances an eye may be lost in twenty-four hours, and, even with the most careful treatment, there is always grave danger to vision. This should never be forgotten when a case of gonorrhœa is treated, and the physician should take the utmost care to protect himself and should warn his patients. Cases are not infrequent where innocent persons are infected with this disease from public towels and the like, and it is our duty to instruct our clients to avoid such criminal carelessness as will endanger others, and to deprecate the inexcusable practice of using such dangerous articles in the toilet as those found in any public place.

Glaucoma, too, is a disease which the student should be taught to be on the lookout for and against which he should be warned. Many an attack of acute glaucoma has been allowed to go on to hopeless blindness without an effort being made for its relief, because it was believed to be a bilious attack. It is not always easy to test the tension of an inflamed eye, but when a patient, who seems to be suffering from what would ordinarily pass for a bilious attack, is found to have an inflamed and painful eye, the possibility of glaucoma should be always kept in mind. It may be added in this connection that it is, as a rule, dangerous to use atropine in patients over forty, as it is believed to sometimes precipitate an attack of glaucoma.

We should likewise emphasize the fact that there is such a disease as sympathetic ophthalmia. We can not hope to enable every student to recognize the disease, but we can teach him that when one eye is injured, especially should that injury affect the ciliary body, or should a foreign body be located in the globe, there is always danger that the fellow-eye will be affected, and that it will often

become the more hopelessly blind of the two. Again, when the patient has an eye which has been lost through some previous injury, should this eye, even though reduced to a mere stump, be tender on pressure, it is a menace to the sound eye, and it is a safe supposition that any irritation arising in the sound eye under such conditions is the beginning of sympathetic ophthalmia.

In strumous children eye diseases are of frequent occurrence. In these cases it should be remembered that attention to the general nutrition is of the highest importance. A strict regulation of diet is imperative. We usually find that these little sufferers are given pie, cake, candies, tea, and coffee, to the exclusion of more wholesome food. The effects of such a diet are obvious. They are allowed to spend most of their time indoors, where, as a rule, the surroundings are most unhygienic, and, if left to themselves, they will select the darkest and most unsavory corner of this retreat, where they will spend the entire day with the head buried in the pillow. When it is necessary to take them out, as for their visit to the doctor, the eyes are tightly bandaged, and in the class of patients which I have in mind—namely, those seen at the public clinic—the preference is usually given by the parents to the thickest, wooliest, and dirtiest material at hand for a bandage. The bandages should be removed and the patient be sent into the fresh air; this, with a rational diet and the administration of some tonics—as, for example, the iodide of iron—will do as much as local treatment, often more, to relieve the patient.

One of the most important points relative to diseases of the eye which the general practitioner is frequently called upon to decide is whether, in any given case, some error of refraction or anomaly of the ocular muscles is the exciting cause of headache or some reflex nervous symptom. That such eye defects are a frequent cause of headache and reflex nervous disturbances no careful observer can deny. We must not allow our enthusiasm to carry us to the point of believing that all headaches, all nervous symptoms, and the majority of other physical disorders, have their origin in some eye defect; but it is a safe proposition, and one easily verified in practice, that, in a very large proportion of headaches and in a certain lesser proportion of nervous disturbances, eye defects are at least a contributing, if not an exciting, cause.

My experience has been that, almost without exception, in patients suffering with these symptoms, arising from whatever cause, when an error of refraction or lack of muscular equilibrium was found to be present, the correction of such defects benefited, if it did not cure, the headache.

I think in some of these cases treatment directed to the stomach, pelvic organs, nose, or other source of irritation would likewise have relieved the patient. The nervous system might be able to struggle along comfortably with an irritation arising from one of these causes, but with the two it could not successfully cope. In many cases none will deny that the eye defects give origin to most distressing headaches, and to nervous reflex symptoms, some of which seem so remote that, unless the case is actually before one, it is sometimes impossible to believe that any connection exists; yet the explanation is simple enough. Let any one

of us place before one eye a prism just strong enough to give the slightest possible separation of images in the vertical, in a few moments the presence of such a glass becomes simply intolerable and enables one to more easily understand how such a source of irritation, when present for a long time, can give rise to a condition of nervous hyperæsthesia, which may manifest itself in any of those myriad ways in which a disordered nervous symptom finds expression.

Such being the importance of eye defects in the causation of those diseases with which the general practitioner has every day to cope, it follows that no careful practitioner can afford to overlook them.

The question then naturally arises, How far and in what manner shall we proceed in an examination to determine the presence of such ocular defects? The ophthalmoscope, which is highly recommended by some ophthalmologists as an easy and reliable method of determining the refraction, we must exclude on the grounds already given, and even when used by one perfectly familiar with its employ, I believe its findings to be only approximate. A test which any one can make is that of visual acuity. A card of test letters, such as can be obtained at any optician's, can be hung on the wall of the office, and the patient, standing at a distance of twenty feet from the card, be allowed, with each eye separately, to read the lowest line that he can discern. Should he be unable to read the line marked XX or better in a moderate light, it is evident that he has some visual defect.

Astigmatism may sometimes be detected by the very simple expedient of allowing the patient to look at a chart composed of radiating lines, such as are sold for this purpose. Should the lines not appear of uniform distinctness, but those running in one direction—say horizontally—are clearer and brighter, as if printed in better ink than those on the rest of the chart, and if these lines rotate as the position of the head is changed, the patient undoubtedly has some astigmatism.

These simple tests are valuable if they serve to discover some eye defect, which may offer an explanation of the symptoms. But even should a patient pass both of these examinations successfully, we can not exclude eye defects. It is in cases of hypermetropia and hypermetropic astigmatism that headaches and reflex disturbances are most frequently found, and these defects are often concealed by the action of the ciliary muscle. In young subjects it is rather the rule that they are so masked. The patient sees well, both at the far and near point, and possibly nothing save a slight feeling of fatigue after using the eyes, sometimes not even this, points to the eyes as a source of headache. I know of no easy test by which these cases can be detected. If the patient's time is of no consequence, a solution of four grains of atropine sulphate to the ounce may be instilled into the eyes for two days, and then another test of vision made. If the visual acuity has markedly declined, it is then evident that some refractive error was covered by the ciliary muscle.

When it is impossible to obtain an examination under atropine, I know of no means by which the physician can

exclude eye strain as a possible cause of these symptoms. He must then inquire very carefully into the habits of the patient and the nature of the headaches—whether they are apt to occur with greater severity after the eyes have been put to some unusual strain; whether the patient is usually better after a holiday or a Sunday; if the patient is a child in school, whether the suffering is aggravated by a return to work after the vacation; and from such data must make up his mind as best he can whether an examination of the eyes is indicated or not.

These suggestions will apply equally well to muscle cases.

This subject is one which I always approach with many misgivings, not because I do not believe that abnormal relations of the ocular muscles are a frequent cause of the symptoms which we have just been considering, but because I am so thoroughly impressed with the great difficulty so frequently found at arriving at a correct diagnosis of these cases. They are by all odds the most difficult and troublesome cases with which we have to deal; there are no simple and ready tests for the detection of muscular defects; each case requires a careful and personal study; a defect which in one person gives rise to no inconvenience whatever will in another totally incapacitate the patient from eye work. You may examine a patient again and again with a perfectly negative result, and finally, when utterly discouraged, find some muscular anomaly, or again the findings of different examinations may be entirely contradictory.

Having determined what the muscular defect is, one is then by no means relieved of embarrassment; patients will often experience the greatest difficulty in wearing prisms, and it is a frequent experience to find the glass which corrects the muscular defect, and which, persevered in, cures the patient, will at first increase his sufferings tenfold. The operation of tenotomy is highly lauded for the relief of these troubles, but I believe it should be undertaken with extreme caution. A very little experience suffices to convince one that the muscular relations are by no means constant; it is a very simple matter to change a pair of glasses when they no longer meet the requirements of a case, but it is not so easy to undo the results of an operation, and I am unwilling to operate until the patient has been under observation for a sufficiently long time to convince me that the muscular condition is a constant one.

Of the simpler tests for the detection of muscular defects, perhaps the best is made by placing before one eye of the patient a prism of say  $7^\circ$ , with the base up or down, and directing him to look at the flame of a candle twenty feet distant; if the two images which he now sees are not directly one above the other, there is lack of equilibrium between the internal and external muscles; again, to test the superior and inferior, place a prism— $10^\circ$  will usually suffice—with the base toward the nose; the images will now stand side by side, and should one be higher than the other, a defect is evident. This test is, as I have said, by no means final, but it is sometimes sufficient to discover a defect.

The foregoing suggestions do not by any means com-

prise all that a man can with advantage learn of disease of the eye. Could every student before graduation receive a course of instruction equivalent to what is now given in a post-graduate course on diseases of the eye, the advantage to the public would be incalculably great, but until this is possible, let us endeavor, so far as we can, to impress upon our students a few of these facts, ignorance of which will seriously endanger their patients.

64 MONTAGUE STREET.

### OPHTHALMOLOGICAL PAP.\*

By H. H. SEABROOK, M. D.,  
SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

MY dear friend and brother, the general practitioner, frequently asks why eye specialists do not try to teach him how to know what eye diseases to treat without danger to himself, and he says he wants this given in a simple manner in a treatise that he can understand, not for fine diagnosis of eye disease, but merely—

“Distinguishing those that have feathers and bite  
From those that have whiskers and scratch.”

“For,” says he, “I send several patients in succession to some eye specialist, who return and upbraid me when they are told that their trouble is an extremely simple one, which any medical man ought to recognize. Tired of this, I treat an apparently simple case myself, and the next thing I hear is that my patient has gone to a specialist and been told that the man who has used atropine on that eye with glaucoma ought to be put on ice if he ever has a chill.”

During the next twenty minutes I shall not endeavor to raise you from your present condition of dense ignorance to a perfect knowledge of the differential diagnosis of eye diseases. For any such consummation the general practitioner is referred to some school for post-graduate instruction. The task I have set myself is, perhaps, more difficult—viz., to write a paper containing a few general points about eye diseases in such a manner that the members of this society can understand it. Consider the price of success, gentlemen, and pity me. What manner of treatise must it be?

Many patients complain of water running from the eyes. This may be due to slight conjunctivitis or congestion of the lids; sometimes from improper correction or lack of correction with glasses. Overflow of tears, due to trouble with the lacrymal canals, may be diagnosed by pressure upon the lacrymal sac, when mucus or pus will flow back at the inner angle of the eyelids. This latter condition is usually consequent upon disease of the nose and stricture of the nasal duct. If the stricture is above the lacrymal sac, the contents of the sac will empty downward upon pressure. Many of these cases require operation. There is one class of cases, however, requiring special mention. There is chronic irritation of the lids, even inflammation, with a granular condition in certain

cases. The correction of the eyes with glasses has been attended to. The condition of the lids is relieved by local treatment, but relapses occur. The eye symptoms being severe, the patient refers the trouble entirely to the eyes, rebels against treatment of the nose, and is surprised at the relief to the eyes afforded by such treatment. The trouble starts in the nose primarily and extends up the lacrymal canals. This is the way in which the nose affects the eyes, and it requires a robust imagination at present to conceive diseases of the nose as causative in any eye diseases except, quite frequently, in conjunctival inflammations and occasionally in corneal troubles. When the lids are stuck together upon the patient awakening from sleep, there is conjunctivitis. You may consider this a diagnostic sign of acute conjunctival inflammation. In my experience the general practitioner is, in one way at least, extremely modest. He confesses that he knows little about eye diseases, but often coyly admits that he knows conjunctivitis. Since, however, he is apt to call it by another name and use atropine locally in its treatment, it may be well to hint that while his standpoint may be entirely correct, it differs slightly from the conventional one which obtains among ophthalmologists, that in conjunctivitis the lining of the lids is inflamed and that the quality of the congestion upon the eyeball is of more diagnostic importance than the quantity: long, tortuous vessels appearing over the white of the eye in conjunctivitis, short, straight, numerous vessels being seen at the corneal margin in central inflammation (of the cornea or iris). Mucopurulent or purulent secretion occurs only in conjunctival inflammations, and it is the presence of this in front of the pupil, with consequent haziness of vision and distortion of objects, that causes the complaint of “poor sight” and “seeing double.” This condition is momentarily relieved after the lids have been gently rubbed while closed, as there is no real trouble with the sight. Patients frequently complain of pain instead of a smarting or gritty sensation when the conjunctiva is inflamed. In the male German who weighs over two hundred pounds, conjunctivitis appears to cause at times the most acute suffering, much aggravated when the lids are slightly touched. However, it is customary to consider a genuine all-wool pain in the eyeball or forehead as symptomatic of neuralgia, iritis, or inflammatory glaucoma. In supra-orbital neuralgia there is tenderness over the affected nerve, and the sight of the eye is not affected. In iritis the pupil is contracted, the iris is sluggish or immovable and discolored, the pupil has a more or less hazy look, and there is the characteristic injection about the cornea. The sight is affected more or less. In inflammatory glaucoma the pupil is *dilated*, the iris is discolored and immovable, the structures in front of the pupil are hazy, with a greenish-yellow reflex from the pupil, and there is the circumcorneal injection with injection of the veins just over the sclera as well, the iris is pushed forward toward the cornea, and the sight is very much impaired. In addition, there is corneal anesthesia, and upon pressure over the center of the eyeball through the upper lid while the patient looks down, the affected eye will be found to be harder than the sound one.

Now, glaucoma should be treated by means of eserine or

\* Read before the Lenox Medical and Surgical Society, December 14, 1891.

an iridectomy. You all remember Artemus Ward's Chinaman sailing down the flood in a wash-tub when asked by the drowning man to throw him a rope. His reply—"No have got, how can do?"—has always been considered a valid excuse for non-performance of duty even in California. When a medical man meets with a case of acute glaucoma late at night about five miles out from New Egypt, he knows that the nearest druggist would not know what eserine was if he should send for it, he has no instruments for an iridectomy, and does not know how to do one any way. It is best in such a case for him to give a hypodermic of morphine, apply heat in the form of frequent douching to the eye, and hope for the best.

The many forms of corneal disease have several signs in common. Photophobia is the characteristic subjective symptom. Objectively there are one or more opaque spots upon the cornea and the pericorneal injection. Cocaine should not be used indiscriminately in these cases. Eserine (not stronger than half a grain to an ounce in a fresh solution) should be used in glaucoma and deep marginal ulcer of the cornea. It is dangerous in iritis. Atropine may be used in the other diseases of the eyeball. It is a cause of irritation in conjunctivitis, it is "rank pizen" in glaucoma, and it can not be used in all eyes without external inflammation, especially in persons past middle life, without decided injury to some of them. Heat should be used in diseases of the eyeball, except just after a burn or other injury and where there is hæmorrhage. Cold is better for conjunctival inflammations, injuries, and hæmorrhages. The subject of injuries of the eyeball is an extremely complicated one, but in treatment cold and atropine, with antiseptics when the tissues are lacerated, are indicated at first. Subconjunctival ecchymosis in young subjects from injury, coughing, or straining, has usually no unpleasant significance. Cold to check it, with heat later to promote absorption, may be used. The practice of attempting to wipe off the spot with the corner of a handkerchief is, so far as I know, indulged in by no one except an occasional medical student. In subjects no longer youthful, subconjunctival hæmorrhage may be significant of some general circulatory or local ocular disturbance. Excepting tumors, there are but three other appearances upon the white of the eyeball needing consideration here: a livid swelling signifying episcleritis; a vesicle with more or less swelling at the base (phlyctenule); lastly, a horizontal more or less triangular thickening of the conjunctiva, usually on the nasal side of the eyeball, yellowish, and somewhat vascular, having an apex upon the cornea from which it spreads peripherally (pterygium).

When the eyeball is inflamed, especially in iritis and injuries, it sometimes develops extreme tenderness upon the lightest pressure just back of the corneal margin. This is the diagnostic sign of an inflammation of the ciliary body (ciliary processes and ciliary muscle), and *that* inflammation means business.

Many general practitioners possess two cards for testing. One is placed at a given distance and the patient asked to read the letters marked as being appropriate to that distance. The other presents in small type a statement to the

effect that if it can not be read at twelve inches glasses are needed. The further statement that floating spots before the eyes indicate nervousness is probably put in to fill space, being both irrelevant and misleading. You all remember how Captain Cuttle acted when Florence Dombey fainted. Having a notion that a watch and a physician were in some way connected, he hung his famous repeater on the hook that was attached to the stump of his arm and then waited to see if the watch would not do something. The faith displayed by many men in the test cards above mentioned is as entirely misplaced as Captain Cuttle's in the efficacy of the watch. Failure of central vision, if recent, is an indication of ocular disease, but disease may exist in eyes that see the proper conventional letters at twenty feet. As regards the diagnostic and prognostic significance of the condition of the eye in certain general diseases little need be said here. Much is written already upon this subject, and with the increase in the crop of young specialists and consequent struggle for ophthalmological existence more and more will be heard regarding it. Poor sight for distance may also mean that glasses are needed, but certain symptoms indicate the necessity for ocular treatment just as definitely. These are a feeling of fatigue or pain in the eyes, congestion of the lids, especially redness at the edges, dull ache in the forehead, temporal headache on one or both sides, pain in the muscles at the nape of the neck extending sometimes downward along the spine, perhaps combined with nausea and dizziness.

Double vision—*i. e.*, seeing two distinct images of an object either temporarily or permanently—may indicate grave ocular or cerebral difficulty. Lack of parallelism of the axis of the eyes in any position, decided inequality of the pupils, and the drooping of a lid coming on suddenly, are signs usually of grave import.

Of late years there has been an unusual waste of medical energy in discussing the influence of the eye upon the general system. Without entering into the discussion regarding eye-strain as a cause of hæmorrhoids, or whether the colic of infants is due to the irregular action of their ocular muscles, it is absolutely necessary for an ophthalmologist to give consideration to the abnormal eye as a source of irritation to the nervous system. Man is comparatively easy of medical comprehension. We know he is a liar on the authority of David, probably a fool according to Carlyle, and by the indisputable dictum of Moses and Sayre that he ought to be circumcised. The cause is somewhere near the effect as regards his symptoms, and when his brain or spine is affected it is considered good judgment to start off with full doses of iodide of potassium. With the modern American woman, however, it is somewhat different. Almost any nervous manifestation on her part may be due to some irritation in any situation in the body or out of it. Just at present the dress reformers have had to take a back seat. Who could consider the vulgar corset as a cause of woe when once hypophoria had been mentioned in opposition? So the eyes have the call at present, and the general practitioner is invited, by means of various more or less scientific articles in the medical journals, to bathe his patients with various nervous symptoms in

the ophthalmological font. There is an accepted standard as to what an eye ought to be, but some people with eminently proper eyes suffer from eye-strain, and other reprobrates with eyes that ought to give a horse the blind staggers are exasperatingly comfortable. As a rule, of course, defective eyes cause definite trouble when much used, which can be more or less relieved by local eye treatment. When an eye is corrected as nearly as possible up to the scientific standard, this may or may not be the proper standard for the individual case, and the correction must accordingly frequently be more or less modified. As if this were not troublesome enough, the ocular muscles must be considered, as so much trouble may arise from their defects. No two men have as yet agreed as to what the standard muscular arrangement should be for the standard eye. As to the modifications suitable for the different variations in refraction and the different kinds of people, no one has the slightest idea.

There are many cases with conditions of the ocular muscles well recognized as abnormal, and definite symptoms which can be referred to the eyes with certainty. Usually improvement of the muscular condition causes improvement of the symptoms, sometimes the eyes get better and the symptoms get worse, and occasionally the symptoms disappear while the ocular condition gets worse.

The arrangements of modern civilized life are seen to be entirely inadequate to the situation when we reflect that the ocular muscles seem to be becoming more and more peculiar and troublesome, while profanity has made no advance since Washington fought the battle of Monmouth.

118 EAST SEVENTY-SECOND STREET.

NOTE.—Reading the foregoing has shown the inadequacy of the remarks about the local use of cocaine and atropine. Cocaine sometimes causes superficial ulceration of the cornea. The danger of this may be avoided to a certain extent if the surface of the globe is kept moist or covered from the air. Its effect upon the ocular circulation is not always a desirable one. The danger from the use of atropine in the eyes in old people is in the production of glaucoma in hyperopic eyes with shallow anterior chamber, or in the bad effect upon such eyes when an insidious chronic glaucoma may have already begun to develop.

## REPORT ON CAPITAL PUNISHMENT,

BY A COMMITTEE APPOINTED BY  
THE MEDICAL SOCIETY OF THE STATE OF NEW YORK  
IN ITS SESSION OF 1891.\*

BY A. JACOBI, M. D., NEW YORK, CHAIRMAN;  
W. C. WEY, M. D., ELMIRA;  
B. F. SHERMAN, M. D., OGDENSBURGH.

CAPITAL punishment has engaged the attention of all classes of men, in and out of office—citizens, lawyers, clergymen, legislators, and philanthropists. It has gradually, under ordinary circumstances, been restricted to such persons as have taken the life of a fellow-being. Those in its favor allege the propriety of retaliation, which, among so-called civilized men, becomes the exclusive privilege of the communities, and justify their position by referring to the Bible and the dictates of religion.

Those opposed proclaim their respect for the sacredness of human life under all circumstances, deny the right of the state to destroy it, and protest against the community's imitating in cold blood the example of the very murderer whom it execrates for his brutality and cruel cowardice; they point to the degrading influence of executions, and also refer, as their justification, to both the Bible and religion. Thus capital punishment is both condemned and authorized by religionists, for the same reason that slavery, but thirty years ago, was both justified and censured.

The questions engaging the attention of this Medical Society of the State of New York are always scientific; they are practical only so far as they are dependent on and based upon science. No matter what any of our members believes or acts upon as a private citizen outside this hall, and outside the legitimate labors of his professional life; no matter what his political party allegiance is, or his creed and religious belief, here we are neither lawyers, nor legislators, nor retaliationists, nor religionists. Thus your committee does not propose to ventilate the question of capital punishment, or its perpetuation or abolition, and the subjects connected therewith—viz., the nature of crime, of responsibility or irresponsibility, of the cerebral functions called judgment and will, the existence or non-existence of a free will and its limitations—from any other but an anatomical and physiological, that is, scientific, point of view. Your committee holds that no questions but those strictly scientific and conducive to the hygiene of mankind have any right before your forum. What we must principally avoid is the reference to metaphysical speculations such as that of one of the greatest minds in history, Spinoza. He maintains that "in the mind there is no such thing as absolute or free will, but the mind is determined to will this or that by a cause which is determined by another cause, this by yet another, and so on to infinity." Nor must we allow ourselves to be swayed by an opposite consideration of Huxley's, who contests that "theft and murder would be none the less objectionable were it possible to prove that they were the result of activity of special theft and murder cells in the gray pulp." Objectionable? That they certainly are, for they are anomalies in themselves and disturbers of the equilibrium of social and moral economy. Objectionable they were, both the theft of a sixpenny worth when it was punished on the gallows as late as this very century and that which is forgiven or mildly reprimanded by a humane judge of our time. More than merely objectionable is the murder of a fellow-being, whether it is executed on the gallows, or buried in an insane asylum, or condoned by wire-pulling powers, or justified on the plea of self-defense.

Crime is the result of an evil impulse which ought to have been controlled. The controlling powers are the cerebral functions of judgment and will. Whoever is held responsible for their aberrations and his wrongdoings is termed, and punished as, a criminal. Whoever is considered irresponsible is no longer a criminal to be punished, but a lunatic against whose vagaries society takes pains to protect itself. Indeed, among civilized people, both the punishment of the criminal and the incarceration of the hopelessly

\* Read before the Medical Society of the State of New York, February 3, 1892.

insane are, or ought to be, but different modes of self-preservation. By them the theory of revenge and retaliation has been given up long ago. Their minds are more bent upon the preservation of the physical and moral health of the community than on the spiteful annihilation of the rebel against the common welfare.

The question of responsibility or irresponsibility is a very grave one, both theoretically and practically. The assumption of the adage "no free will exists" would explain and excuse and defend everything either friendly or inimical to the interests of society and the rights of the individual. Still, many high in science and literature and philosophy defend it.

Benedict, one of the best known and deservedly famous physiologists and pathologists of the brain, comes (*On the Brains of Criminals*, Vienna, 1879) to the following conclusions:

"The brains of criminals exhibit a deviation from the normal type, and criminals are to be viewed as an anthropological variety of their species, at least among cultured races.

"The constitutional criminal is a burdened individual, and has the same relation to crime as his next-of-blood kin, the epileptic, and his cousin, the idiot, have to their encephalopathic conditions.

"The essential ground of abnormal action of the brain is abnormal brain structure.

"The appreciation of these facts is likely to create a veritable revelation in ethics, psychology, and jurisprudence."

So it will; though not every crime be dictated by disease, and because the interests of the commonwealth require protecting and saving.

Responsibility and irresponsibility have but uncertain boundary lines. These can not always be determined. They depend on a great many factors which may be fixed or changeable, stationary or transitory. The education of the young, no matter what his cerebral substance or general physical constitution, works only by influencing and changing his brain structure. Disturbances of the health of the body, and particularly of the brain, may either terminate in restitution to the normal state quickly and easily, or with difficulty and late, or no recovery takes place at all. This difference in the result may depend on the severity of the attack, on a congenital disposition which need not assume the significance of a malformation, but shows itself only in differences in the power of resistance on the part of the cells or organs in the individual bodies; in the same way in which an infectious fever destroys the one, injures the other, and leaves the third intact and immune.

These varieties of structure, dispositions, and of powers of endurance and resistance are very interesting. There are many anomalies in the nervous system which tend, according to circumstances, either to recovery or to faulty development. Such are the predispositions, recognizable in infancy and childhood, to neuralgia, nervousness, melancholia, misanthropy, eccentricity, dudism, hysteria, hypochondria, inebriety, convulsions; the tendency to cardiac, vascular, and vaso-motor irregularities, such as palpitations, fainting spells, vertigo, sudden congestions to brain and

face. They are neither diseases nor crimes, but they may lead to both. Favorable or untoward influences determine the development of a hypochondriac into either a famous humorist, who makes tens of thousands of sturdy men smile through tears, or a homicide, who sends a shudder through men and women; or a boy suffering from congestive headaches may develop either into a heart-moving and soul-stirring poet or a raving maniac. For normal growth and exaggerated overgrowth are but two different results of the same vascular action.

The adult man or woman is the result of hereditary and congenital structure and disposition and a thousand influences of mental or physical nature. The former are but nominally different from the latter. Education is but the shaping of the brain by impressions, the consequences of which are physical, no matter whether they are permanent or transitory. When the former, they impress even the features of the face; deep must be the delineations in the nervous center which are permanently photographed outside. Thus there are educational crimes like social crimes. The formation of the earliest habits is the determination of the character of the man. The dime novel, which spoils the taste and fires the imagination, is as certainly a source of infection as the exhalation of a sewer. Paul Aubry wrote in 1888 on the contagiousness of murder. With him the great factors in inducing it are heredity and degeneration. The latter, according to him, depends largely on education—in its widest sense. He charges the public press with producing crimes by its constant sensational reports which excite the imagination and lead to imitation by the persistent parading of an example. Thus are brought about the acts of cruelty during political upheavals, such as remind one more of insanity than of mere barbarism. His prophylaxis is based upon the same opinions. The prevention of the contagiousness of murder consists in a sound moral, individual hygiene, in the moralization of habits and customs, in proper regulations of the press reports, and in a more logical severity of the courts of justice.

Many of the physical changes which lead, or can lead, to criminality are preventable. The servant girl who lets a baby fall may maim it for life, or may so affect the brain as to change the current of thoughts and feelings into criminality. The development of a syphilitic infant into either a healthy man or an invalid, or the luckless possessor of a cerebral endarteritis or gumma, with their physical or moral consequences, depends on the diagnostic knowledge and the therapeutic agents of the practitioner. It is he who may be the intellectual father of the criminal. The obstetrician's clumsy forceps, or improper use of forceps, has frequently injured both head and brain. The prolongation of asphyxia in the newly born gives rise to thrombosis, hæmorrhages, and secondary encephalitis, to paralysis, idiocy, epilepsy, or insanity. Thus a few seconds more or less, thus obstetrical knowledge and dexterity more or less, may decide the fate of the newly born, his physical, intellectual, and moral health or invalidism, and his whole future forever. Or contemplate a few large rachitical heads a few years old after the disease has run its full course. Their circumference

and shape are probably the same; ossification has been completed for some time, and no great alterations will ever take place. In all of them rhachitis was mostly cranial and cerebral. One has attained a normal development, one has developed an unusual amount of brain in the vacant space, and the vascular irritation has added to its vitality and evolution into the growing genius; the last is a confirmed hydrocephalus with its future semiparalysis and idiocy. Why these differences? Why—in one case the condition was recognized in time and treated judiciously; in the other some domestic absurdity of diagnosis—difficult teething—was furnished by the ignorant mother and meekly accepted by the medical man. Thus the same big head may mean either perfection or incompetence, and it takes more than a jury of fellow-citizens to decide what is going on inside.

Psychical diseases or anomalies, both acute and chronic, are frequent under toxic influences. Infectious diseases in their acute stages give rise to acute attacks quite often. Scarlatina, typhoid and puerperal fevers, poison the blood and impair cerebral action by the mere circulation of the ptomaine, though there be no complication with meningitis at all. Even in children, insanity, both maniacal and melancholic, has often been met with in and after infectious fever. Many of the child murders during the puerperal stage were the results of puerperal infection. Opium and the other narcotics—belladonna, hyoscyamus, stramonium—have similar results of the depraving both judgment and will-power. The chairman knew a woman who took at once a number of doses of cannabis which were given for medicinal purposes, and in her jocose aberration of mind was found dancing and singing round the stove on which she was roasting her baby. Next day the medicinal mania wore off. It took hard work to save her from the gallows. Ergot sometimes, more frequently iodoform, oxide of carbon, and the sulphide of carbon of the India-rubber works act in the same way. And alcohol? The delirium tremens and its many criminal acts fill the records of both the hospitals and the courts of justice. Still more dangerous, because more numerous, are its chronic effects. Its ethical depravation equals its æsthetical ugliness; mendacity, feebleness of will-power as bad as physical tremor, idiotic torpor, and the delirium of jealousy and violence, the habit of idleness and tramping, thieving, and outrages of all kinds—are the mottoes inscribed on its flag. Acute lead poisoning leads often to the same symptoms as that of alcohol—sleeplessness, hallucinations, and violence like those of delirium tremens; and its chronic influence leads to results resembling those of progressive paralysis. Your committee merely mentions cocaine, chloroform, chloral, bromides, to remind you of the many external influences which may slowly, silently, and surely so alter the cerebral substance as to result in functional anomalies which, if understood, if recognized through that mute and hard cranial shell, as what they are, would be called diseases; when they are not they are called crimes.

The anatomy and physiology of the brain are greatly under the influence of the heart. Many chronic and some acute cases of dementia can be explained in this way. It is always the chronic class which is more dangerous because

it is more difficult to notice and guard against. In many of them atrophy, hypertrophy, or congenital smallness; in others, adiposity or fatty degeneration, or stenosis of the aorta, with its consecutive cerebral auæmia and ill nutrition, or the obliteration of the pericardium; in very many the incompetent mitral valve, with its retarding influence on the intracranial circulation—is a cause of insanity or insane actions. The latter precede the recognition of the former a long time. A man whose name was prominently mentioned in connection with the New York dynamite affair was repeatedly before the courts for assault and battery and attempts at murder before his condition, appreciated and predicted by a member of your committee, was finally acknowledged.

The diseases of the brain whose influence on and connection with mental and moral diseases is undoubted are either local or general. In many no other symptoms could be discovered, in others the intellectual and moral anomalies were complicated with other symptoms. To that class belong tubercles, which are quite common in demented persons, syphilitic changes, abscesses, either from emboli or atheromatous degeneration, neoplasms of different nature, and multiple sclerosis. Very frequent is apoplexy either from vascular incompetency or traumatic. A boy of eleven years, under the observation of the chairman of your committee, fell from a tree and had convulsions which lasted for hours until hemiplegia set in. While his paralysis was slowly improving, he exhibited furious attacks of violence with attempts at murder, and finally epilepsy, all of which improved after several years, leaving a moderate degree of paralysis.

Of the diffuse affections of the brain we shall only mention inanition from physical causes and from overwork and anxiety, and exhaustion from excesses, insolation, trauma, and other causes of hyperæmia and meningitis. Here belongs periencephalitis, which may begin slowly with physical symptoms, or with mania and hypochondriasis. Senility is a frequent cause of mental disturbance. Unfortunately, the symptoms of most of these conditions may resemble each other very much; delirium, mania of all kinds, mainly persecution mania, puerility, irascibility, diffidence, misanthropy, are just so many symptoms of both acute, subacute, and chronic forms. Epilepsy is a frequent cause of outbreaks of unexpected violence. This peculiarity gave it the name of propulsive epilepsy. Many criminal acts are the positive results of epilepsy, and many epileptics were cured on the gallows. At this moment a negro is under trial for a murder. He is known to have severe attacks of epilepsy. Experts have sworn he is a criminal. Experts have sworn he is diseased and not responsible. What does it teach? It teaches that there is surely reason for a doubt as to the causation of the criminal act. It would also teach that society as represented by the jury, and that society, representing the humane spirit of the times, ought to keep a sharp lookout to its own dignity. Man may blunder, but society can not afford to be brutally mistaken where it is at the same time accuser, judge, jury, and executioner.

The malformations of the male sexual organs, mainly anorchis and diminutive development of the penis and testi-

cles, predispose to mental degeneration, with its consequences. One of your committee knows a man of thirty-six with infantile organs and no trace of hair on the pubes. In spite of repeated warnings not to expose himself to utter failure, he attempted cohabitation. When alone with his partner he grew moody and desperate, becoming more than ever aware of his incompetency. In his rage at rendering himself ridiculous he attempted to strangle the woman; she finally succeeded in saving herself and delivering him to the police, which landed him in a penitentiary. Masturbation and emissions produce melancholia and mania; in milder forms depression, despondency, and moral obliquity. If you wish an example of monomania resulting from masturbation and excessive venery, take that of a man otherwise gifted and in high esteem for many personal qualities—Tolstoi. His *Kreuzer Sonata*, the hero of which is evidently an autophotograph, is the nastiest and most vulgar glorification of male impotence and consequent moral depravity possible. It is again the class of masturbators which furnishes part of the disgusting tribe addicted to sexual perversion, such as pæderasty, sodomy, and homicidal mania. Nymphomania I have not mentioned, because its complication with homicidal mania is but rare. But the influence of the great developmental periods—puberty and the climacteric age—in the production of moral morbidity is well appreciated.

Great difficulty in deciding the nature of a criminal insult is experienced in cases of periodic insanity. It is these cases which are received in lunatic asylums, retained for a short time, and then discharged cured to exhibit favorable statistics, or are freed by the philanthropic cranks, who mistake a hospital for a dungeon. The dangers of such premature or unauthorized discharges are great indeed; the daily press reports from time to time homicides and murders committed by men who ought to be protected against themselves and prevented from doing harm to others by being locked up for life. Intervals between acute attacks of mania or melancholia may last years; particularly, cases connected with epilepsy come suddenly like a flash. Moon and sun, terrestrial magnetism, and the electrical condition of the atmosphere, climate, telluric exhalations, intervening diseases, be it only influenza, wounds, or other debilitating influences of short duration—are apt to give rise to violent outbreaks. In such cases the decision as to whether the accused was a criminal or a sick man when the murder was committed is very difficult or even impossible. Years after the occurrence the diagnosis of the case must be attempted. The history of previous cerebral disease, of *petit mal* or full-grown epilepsy, neuroses and fainting spells, eccentricities, hallucinations, possible heredity will be told with more or less significance. These are the very cases which prove unmistakably that insanity is not always typical and constant in its nature. Doubtful conditions are very frequent. And in the face of these facts a jury is expected, under the spur of one attorney and the derision of the other, to find a verdict of responsibility or irresponsibility. These are also the facts which have induced the Germans to establish the principle of a partial responsibility.

When a crime is made the subject of investigation the

perpetrator ought to be subjected to the closest study. The action of an engine is not estimated or calculated without considering the shafts and wheels and boiler; but the changes of judgment and will are weighed too often by the so-called common sense of the illiterate or semi-educated. No matter whether Benedict and Lombroso are right or wrong, these facts are incontrovertible. You meet too large heads, too small heads, asymmetrical heads—such as you find so very often in epilepsy and idiocy—asymmetrical faces, disproportion between skull and face and their single parts; also disproportion between other parts of the body, excessive length of extremities, big mouth, overgrown tongue, the roof of the mouth too much arched or too flat, and the teeth irregular; the top of the head or the occiput flattened, hare-lip and cleft palate, heavy lower lip, deformed ears, and different colors of iris. There may be the retracted nasal insertion and the shortened base of the skull of the cretin or semi-cretin, or early neurotic symptoms—such as hysteria, chorea, epilepsy, night-terrors, and tachycardia.

Suicidal tendency with the result of repeated attempts at self-destruction is but rarely the result of instantaneous despair or despondency. In many cases the actors in that drama had an organic disease—among them leptomenigitis in all its forms, sclerosis, syphilis, embolism, gray degeneration, adhesions, and cysts. Acute and isolated attacks are often the results of fever, in pneumonia, pleurisy, meningitis, typhoid fever, or influenza. And these are, in part, the cases which are thought worthy not of the hospital, but of the penitentiary.

*Conclusions.*—There are many causes of the perversion of judgment and will.

These causes which are physical are either congenital or acquired. When acquired, they are so either by the progressive development of hereditary or congenital disposition, or by intervening diseases, or by the impairment of cerebral evolution through bad training, example, and social influences.

The variety of causes, both anatomical and functional, is such as to render an exact diagnosis extremely difficult. The sworn opinions of experts are quite often contradictory. Cerebral anomalies and lesions are very often not accessible to our methods of investigation.

When there is any doubt in an individual case of crime in regard to either responsibility or irresponsibility, it is safer to take the alleged criminal to be diseased and morbid than to declare the sick to be a criminal.

In many cases the innocent and the anatomically sick have been subjected to capital punishment. On the other hand, dubious cases developed full-grown dementia soon after the criminal proceedings.

The knowledge of such occurrences is part of the reasons why juries are averse to rendering the verdict leading to a death penalty, and why but a small percentage of murderers are ever sentenced among us, and why so many are set free to become permanent dangers to the safety of the public.

Human society and the state, while they owe protection and safety to all, must make no mistake unless it be in the direction of leniency and humanity.

The medical profession must not allow mistakes to be made which can be prevented. This Medical Society of the State of New York—having the advantages of physiological knowledge and being aware of the difficulties of being always correct, and of the absolute impossibility of making a positively safe diagnosis in every case of alleged crime or presumable cerebral disease or anomaly—expresses its opposition to the perpetuation of capital punishment and its hope that means will be found to protect the community by less uncertain and less inhumane methods.

## TÆNIA

AS A CAUSE OF PERSISTENT INTERCOSTAL NEURALGIA,  
ALSO OF THE ERUPTIVE FORM—*I. E.*, HERPES ZOSTER.

By CHARLES C. DURYEE, M. D.,  
SCHENECTADY, N. Y.

A LITTLE over a year ago the writer was called to attend A. W., aged twenty-eight years, for severe pain over the left side of the thorax. The pain had appeared about a week previous to my first visit, and had been growing severer and confined him to his bed. Tenderness along the seventh and eighth intercostal nerves was made evident by pressure. The diagnosis was intercostal neuralgia, which, perhaps, might be the precursor of herpes zoster. Various remedies were tried with little or no result. Morphine was administered in sufficient quantity to render his distress at all bearable. Matters continued thus for about two weeks, when my patient called my attention to some segments of tape-worm which he had that morning passed, the first he had ever observed. Treatment for tape-worm was promptly given, with the result of dislodging a worm of about the usual length. The pain in the side rapidly began to subside, and Mr. W. was soon at his business.

A short time after, a gentleman sent for me who had a severe and typical herpes zoster. At my suggestion he examined his stools for a day or two and discovered that he was infested with tænia. Treatment resulted in a worm being removed about twenty-eight feet in length, probably a beef-worm.

Since my attention was drawn to the first case related I have seen eight cases of tape-worm, in which four of the persons had either severe intercostal neuralgia or undoubted shingles.

Herpes zoster is an expression of more or less acute neuritis of the intercostal nerves, as are also many cases of intercostal neuralgia.

The causes of these severe and oftentimes persistent diseases are obscure and are given as compression, nerve injuries, operations, atmospheric changes, etc.

I have never seen the presence of tænia given as a causative influence in these troubles, but I am of the opinion that it is of more or less frequent occurrence, and that those affections are probably reflex symptoms of the digestive disturbances occasioned by that parasite. Be that, however, as it may, the foregoing suggestion may be of practical utility in some obscure and annoying cases.

**Constipation.**—"Dr. Platan, of Berlin," says the *British and Colonial Druggist*, "suggests a remedy for inveterate constipation. It consists in the introduction of a pinch of finely powdered boric acid into the bowel. The results are declared to be most satisfactory, even in severe cases, in which mechanical measures had failed to afford relief."

THE  
NEW YORK MEDICAL JOURNAL,  
*A Weekly Review of Medicine.*

Published by  
D. APPLETON & Co.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, MARCH 5, 1892.

### THE LEGAL LIABILITY OF HOSPITALS IN CASES OF ALLEGED MALPRACTICE.

FOLLOWING close upon the recent dismissal of a suit against Dr. William T. Bull, of New York, for alleged malpractice, comes another important decision in which Judge Giegerich, of the Court of Common Pleas, dismisses a suit brought against the Society of the New York Hospital. A young boy sustained a simple fracture of the femur and was taken by his father to the New York Hospital, where splints were applied in the usual way. Three or four days afterward it was noticed that the foot had become numb and cold, and this condition went on to the development of gangrene, which made it necessary to perform amputation through the thigh. The boy's father put in a claim for damages in fifty thousand dollars, alleging that the gangrene was due to gross carelessness on the part of the hospital surgeons in that they had bandaged the limb too tightly. It was proved by the Society of the New York Hospital that the hospital was a public charity, that it had used all due care in the selection of its medical officers, and, consequently, that it could not be held responsible in the case. The court held that this proof released the institution from all liability for injury sustained by the plaintiff.

Although in this case it was shown by indisputable evidence that the gangrene was the result of arterial lesions sustained at the time of the fracture, and that the dressings had been eminently proper, the decision releasing the hospital from liability on account of its character as a charitable institution is of interest in the way of a precedent. It accords with recent decisions made in Massachusetts and Pennsylvania, as well as in this State, but it is at variance with a decision made in a suit brought against the Rhode Island Hospital. So far as we know, the Rhode Island decision is the only American one of importance that does not agree with Judge Giegerich's. The subject is an important one, and it is to be hoped that a definite principle in law will be established in regard to it.

In the first number of the new *International Medical Magazine* the department of Forensic Medicine consists of an article on this question by Mr. Lorenzo D. Bulette, of the Philadelphia bar, who alleges that the American decisions that accord with Judge Giegerich's are based on the precedent of an English decision rendered in 1861, and that that decision is no longer regarded in English courts as of any weight. He cites certain decisions in England practically overruling that of 1861, and quotes from the decision of the Supreme Court of Rhode Island, after which he concludes his article as follows:

"The question, therefore, is, in a certain sense, still an open

one, there being a decision each way. But, in view of the fact that the single case on which the hospitals rely to exempt them from liability has been emphatically overruled in England, and that the later disposition of the courts in this country also is to impose the liability in similar cases, it is easy to predict the result should the matter again come into litigation.

“Following this tendency, the Supreme Court of Rhode Island, after mature deliberation, had no hesitancy in saying that for the neglect of the *interne* to send for the visiting surgeon, as the urgency of the case and the regulations of the hospital required, the latter was answerable. And the same court, guided by the later doctrine laid down in *Mersey Docks vs. Gibbs*, said with equal decision that the income of the charity fund was the source whence to extract the golden balm for the healing of this neglect.

“From all of which we may safely conclude that the relation which exists between a public charitable hospital and its visiting surgeons, physicians, and nurses is that of master and servant; and for the failure of such hospital either to exercise reasonable care in the selection of its servants, or for the negligence and unskillfulness of the latter within the scope of their employment, the hospital must respond in damages to the injured patient.”

#### THE HEALTH OF NEW YORK STATE IN 1891.

THE Summary of Mortality of the State Board of Health for the past year has been received. It shows that there were 123,878 reported deaths, a total requiring a small correction on account of late returns and non-reported deaths from out-of-the-way districts, so that the estimated number was 128,578 deaths. The mortality rate for the year was 21.4 per mille, as compared with 19.6 in the year 1890. The zymotic causes of death were more active than in 1890, but less so than during the last quinquennial averaged period. Aside from epidemic influenza, which disease is not reported in a form susceptible of tabulation, the deaths from zymotic disease numbered 22,000, or 2,300 in excess of the total in 1890 and about the same as in the year 1889. Scarlet fever caused 2,254 deaths, against 913 in 1890. Diphtheria also showed an increase of mortality and was exceptionally active during the summer months, over three hundred deaths from that disease having been registered in the month of July. The midsummer mortality by scarlet fever was high also, July showing 180 deaths. Measles and whooping-cough were most lethal during the first half-year. The deaths from influenza are estimated as having been 10,000, a loss which is double that estimated to have afflicted the State in 1890. The registrar's remarks indicate that the disease was uniformly distributed through the State. Small-pox caused five deaths, or one more than in 1890; this, if true, means less than one death in a million of population, or one death out of 26,000 deaths from all causes. This is tantamount, almost, to an eradication of that disease, a state of things which can not endure many years more in this State, in view of the incoming masses of ignorant, incorrigible immigrants: the outlook is not

favorable to the publication of so good a statistical showing for 1892 as that which has just been presented for 1891. The deaths by typhoid fever and by diarrhœal diseases were more numerous than in the year previous, but were not excessive in number when compared with those of former averaged periods. The deaths by consumption were 13,445, as compared with 13,831 in 1890. This is equivalent to 109 deaths in 1,000 deaths from all causes, a ratio decidedly lower than was observed during the last quinquennium. The ratio has been known, as for example in 1886, to rise to 137 in a thousand deaths. From respiratory diseases, not tubercular, there was the enormous loss of 20,697 lives, which was 2,600 above the loss from that class of causes in the year 1890: and the mortality of each of these latter years has been in excess of that of previous years—a fact that is chargeable in large measure to the influenzal mortality being credited among the various “local” classes. Old age was recorded as the cause of 6,500 deaths. There were 5,028 fatal accidents, or deaths from violent causes. The number of deaths “not classified” was only 15,300, which is less by 3,000 than in 1890, and indicates an improved manner of dealing with the vital statistics of the State.

#### MINOR PARAGRAPHS.

##### INTUBATION.

THERE seems to be little doubt that intubation is growing steadily in favor abroad. In this country, where correct instruments have been used and where instruction has been given so largely by Dr. O'Dwyer and his pupils, the operation has obtained a firm foothold and is far beyond the stage of probation. In England and on the continent of Europe its progress has, naturally, been slower. Reports that have been made, especially from France and Germany, seem to show that ill-constructed instruments have been used. Failures have been repeatedly reported of a character that could not have occurred with proper tubes. Ranke has recently reported, in the *Revue des maladies de l'enfance* for December, 1891, a second series of cases with much more favorable results than had been shown in his first series. In the first he reported 413 cases of intubation, with 34 per cent. of recoveries, and 866 cases of tracheotomy, with 38 per cent. of recoveries. In the series last reported there were 348 cases of intubation, with 41 per cent. of recoveries, and 237 cases of tracheotomy, with 34 per cent. of recoveries. Bokai, after treating 109 patients by intubation, believes that tracheotomy should be abandoned except in a small number of selected cases.

##### A COLLECTIVE INVESTIGATION REGARDING ANÆSTHETICS.

AN exceptionally important inquiry, on a large scale, according to the *British Medical Journal*, is to be made throughout the hospitals of Great Britain, in the year 1892, regarding anæsthetics. Eminent surgeons, anæsthetists, and general practitioners will contribute their clinical experiences, as supplemental to the conflicting results obtained by the experimental workers. The research will be made under the auspices of the British Medical Association. An influential and fairly constituted committee has charge of the plan of the inquiry, and record books have been prepared for the use of those who are willing to co-operate. These books have been carefully drawn

up so as to secure uniformity on the part of the reporters, and they contain full instructions. Mr. Jonathan Hutchinson heads the committee, and Dr. Childs, of Weymouth, is its secretary. Among the other names of committeemen are those of Lister, Annandale, Buchanan, Chiene, Buxton, Duncan, Hewitt, Macewen, Croly, Butlin, and Macleod. The subcommittee for England and Wales is headed by Mr. Pridgin Teale. Similar subcommittees will pre-ide over the work in Scotland and Ireland.

THE AMBULANCE SERVICE OF THE NATIONAL GUARD OF THE STATE OF NEW YORK.

SURGEON-GENERAL BRYANT has issued orders putting the ambulance corps on a somewhat different footing. This corps will eventually be a body of trained nurses. The men formerly employed will, so far as possible, be reappointed, with the expectation that at the end of the present year an advanced examination will be required. The original object was to have ready at hand a certain number of men who could in emergency cases of various kinds, upon the march or in active service, render temporary relief to the sick or injured until such time as the surgical staff could be called upon. This system developed rapidly, and it was found that the members of the corps, not content with the comparatively simple duties assigned to them, pressed onward until they became almost as profieient as trained nurses would be. Some of the Red Cross men joined the classes for nurse-training at the hospitals, and some even took up nursing as a vocation. A very praiseworthy enthusiasm actuates the members of the corps.

TRANSPLANTATION OF THE CORNEA.

A CASE of corneal graft has been reported in the *Berlin klinische Wochenschrift* by Dr. Hippel, of Königsberg. The patient had a dark-brown central discoloration of the cornea three millimetres in diameter and reaching downward to the membrane of Descemet, which had been the result of the action of nitrate of silver. Cocaine was used. The discolored cornea was trephined, down to the membrane of Descemet, with a trephine the crown of which was four millimetres in diameter, and the included disc was carefully removed. The surgeon then excised from the eye of a young rabbit a disc of cornea of the same size and implanted it in the patient's corneal wound. The coaptation was accurately done and the new cornea was at a level with the adjacent corneal tissues. Iodoform was used in the dressing of the eye and both eyes were closed with a bandage. A good recovery was made, and six weeks after the operation the patient was dismissed with a completely transparent cornea.

THE INTERNATIONAL MEDICAL MAGAZINE.

THIS is a new monthly journal of general medicine and surgery, edited by Dr. Judson Daland, and published in Philadelphia, by the J. B. Lippincott Company. The contents for the first number, for February, are of a very valuable character, and the journal makes a good appearance, but the proof-reading ought to be improved.

NEUROTIC INFLUENZA.

DR. C. H. HUGHES, in a recent paper in the *Journal of the American Medical Association*, concludes that the present epidemic of influenza is, in its incipency as well as in its sequelæ, a toxic neurosis, more largely adneurcal than intraneural; that the central or peripheral neuropathic lesions are more prone to recovery than other similar, and apparently as grave, nervous

lesions occurring before the epidemic appeared; that the neuropathic sequelæ resemble post-diphtheritic nervous diseases in their susceptibility to therapeutic measures; and that it brings into activity latent neuropathic and other organic morbid tendencies.

ITEMS, ETC.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending March 1, 1892:

DISEASES.	Week ending Feb. 23.		Week ending Mar. 1.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus.....	16	4	32	4
Typhoid fever.....	13	5	12	13
Scarlet fever.....	209	31	241	35
Cerebro-spinal meningitis.....	0	1	1	2
Measles.....	224	17	339	18
Diphtheria.....	134	35	132	48
Small-pox.....	7	3	4	3
Erysipelas.....	2	0	1	0
Varicella.....	16	0	17	0
Pertussis.....	2	0	1	0
Mumps.....	4	0	0	0

**New Buildings for the Jefferson Medical College of Philadelphia.**

—The board of trustees and the faculty of the Jefferson Medical College have just completed the purchase of two large lots on Broad Street, giving them a frontage of about 300 feet and a depth of 150 feet, upon which they will proceed to erect at once a handsome hospital, lecture-hall, and laboratory building. The estimated cost of the buildings is \$500,000. The hospital will not only be built as a suitable building in which to care for the sick and injured, but also will be provided with a large amphitheatre for clinical lectures. The basement of the hospital building will be given over to the various dispensaries, each of which will be provided with large waiting and physicians' rooms, as well as rooms for the direct teaching of students. The buildings will be absolutely fire-proof, and provided with patent sprinklers in case their contents catch fire. By the erection of three commodious buildings, the laboratories where delicate work with the microscope or apparatus is carried on will be separated from the college hall where didactic lectures are given, and so will be free from any jarring produced by the movement of large classes. With the hospital on one side affording clinical facilities and the laboratory on the other side of the college hall for scientific research and training, the college will be most favorably situated for giving thorough instruction in medicine. Further than this, immediately across the street is the Howard Hospital, and on the adjoining corner is the Ridgway branch of the Philadelphia Free Library, which contains all the scientific works belonging to this wealthy corporation. The new site is even more favorably situated in regard to the center of the city than the old one at Tenth and Sansom Streets. The move has been made necessary by the large number of students who are now being instructed in this institution, and because the faculty desire to keep the school and hospital in the foremost rank of medical education in this country. The buildings will be ready for occupancy in the session of 1893-'94.

**The French Congress of Surgery.**—The *Union médicale* announces that the sixth session will open in Paris on April 18th. The chief subjects of discussion will be: The Pathogeny and Treatment of Surgical Gangrene, The Pathogeny of Infectious Accidents Subjects of Urinary Disease, and Operations on the Biliary Passages.

**Professor Virchow in Defense of his Name.**—The *Deutsche Medizinical-Zeitung* quotes as follows from a letter written by Professor Virchow to the *Vossische Zeitung*: Newspapers from Cincinnati contain advertisements that the "great German Physician," Dr. Karl Virchow Schick, has arrived from Berlin and is prepared for consultations. It is alleged that he has made important discoveries in the "germ treatment of chronic diseases," and that his prescription is being used by 806 physicians in Europe. Allow me to say that, according to the

official registers, there is not and has not been a physician of this name in Berlin or in Prussia, and none such is known in any of the other states of Germany. It is hoped that this notice will induce the American journals to oppose the gentleman's course.

**An Alumni Association of the Ex-internes of the Presbyterian Hospital of New York** was organized on February 19th. Dr. W. K. Simpson was elected president, and Dr. R. R. Ross secretary and treasurer.

**The Chattanooga Medical College** will hold its annual commencement exercises on the 15th inst. Addresses will be delivered by Dr. Robert Battey, of Rome, Georgia, and by Dr. N. C. Steele, of the faculty.

**The Brooklyn Surgical Society.**—The special order for the meeting of Thursday evening, the 3d inst., was a paper on Myoma Uteri complicating Pregnancy, by Dr. Pilcher.

**The Harvard Medical Society of New York.**—At the meeting of March 5th Dr. Coe is to read a paper on The Difficulties in the Diagnosis of Pregnancy.

**Influenza and Life Insurance.**—It is stated in the *Mercredi médical* that from 1890 to 1891 an English insurance company had to pay over a quarter of a million dollars on deaths caused by influenza. This is two and a half times as much as cholera had cost that company in forty-five years.

**Starch in a Fungus.**—"It is a well-known fact that, generally speaking, starch is not found in fungi and those plants which are without chlorophyll; one or two instances have been noted of its occurrence, however, in special cases, and lately M. E. Bourquelot has demonstrated its presence in *Boletus pachypus*. Immediately on touching a section of the boletus with an aqueous solution of iodine and potassium iodide it gives a fine blue tint. The reaction takes place throughout the whole pseudo-parenchyme, but does not occur in the cells of the hymenium or in the sub-hymenial tissues."—*British and Colonial Druggist*.

**The Death of Dr. Charles R. Vanderberg, of Columbus, Ohio,** occurred on February 22d. He was a graduate of the Starling Medical College, of the class of 1885, and lecturer on pathology in that institution for several years before his death, which took place in his thirty-fourth year.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the week ending February 27, 1892:*

MEANS, V. C. B., Passed Assistant Surgeon. Detached from the Naval Hospital, New York, and ordered to the Navy Yard, New York.  
 LANE, GEORGE A., Assistant Surgeon. Detached from the Navy Yard, New York, and ordered to the Naval Hospital, New York.  
 MARSTELLER, E. H., Passed Assistant Surgeon. Detached from the Marine Rendezvous, Baltimore, and to wait orders.  
 CORDEIRO, F. J. B., Passed Assistant Surgeon. Detached from the Marine Rendezvous, Boston, and ordered to the U. S. Steamer Adams.

**Marine-Hospital Service.**—*Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the three weeks ending February 27, 1892:*

PURVIANCE, GEORGE, Surgeon. Detailed as chairman of the Board of Examiners. February 20, 1892.  
 HAMILTON, J. B., Surgeon. Detailed for special duty. February 18, 1892.  
 STONER, G. W., Surgeon. Detailed as member of the Board of Examiners. February 20, 1892.  
 IRWIN, FAIRFAX, Surgeon. Ordered to Norfolk, Va., for temporary duty. February 16, 1892. Granted leave of absence for seven days. February 24, 1892.  
 CARTER, H. R., Surgeon. Detailed as recorder of the Board of Examiners. February 20, 1892.  
 WHEELER, W. A., Passed Assistant Surgeon. Ordered to examination for promotion. February 16, 1892.

VAUGHAN, G. T., Passed Assistant Surgeon. Detailed as executive officer, Supervising Surgeon-General's Office. February 27, 1892.

#### Society Meetings for the Coming Week:

**MONDAY, March 7th:** New York Academy of Sciences (Section in Biology); German Medical Society of the City of New York; Morrisania Medical Society (private); Brooklyn Anatomical and Surgical Society (private); Utica Medical Library Association; Corning, N. Y., Academy of Medicine; Boston Society for Medical Observation; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association (annual); Hartford, Conn., Medical Society; Chicago Medical Society.

**TUESDAY, March 8th:** New York Medical Union (private); Medical Societies of the Counties of Chemung (quarterly Elmira), Rensselaer, and Ulster (quarterly), N. Y.; Kings Count Medical Association; Newark, N. J., and Trenton (private), N. J.; Medical Associations; Baltimore Gynæcological and Obstetrical Society.

**WEDNESDAY, March 9th:** New York Surgical Society; New York Pathological Society; Metropolitan Medical Society (private); American Microscopical Society of the City of New York; Medical Societies of the Counties of Albany and Montgomery (quarterly), N. Y.; Pittsfield, Mass., Medical Association (private); Worcester, Mass., District Medical Society (Worcester); Philadelphia County Medical Society.

**THURSDAY, March 10th:** New York Academy of Medicine (Section in Pædiatrics); New York Academy of Medicine (Section in Genito-urinary Surgery); Society of Medical Jurisprudence and State Medicine; Brooklyn Pathological Society; Medical Society of the County of Cayuga, N. Y.; South Boston, Mass., Medical Club (private); Pathological Society of Philadelphia.

**FRIDAY, March 11th:** Yorkville Medical Association (private); German Medical Society of Brooklyn; Medical Society of the Town of Saugerties.

**SATURDAY, March 12th:** Obstetrical Society of Boston (private).

## Obituaries.

### BUCKMINSTER BROWN, M.D., OF BOSTON.

IN the death of Dr. Buckminster Brown the profession loses the man who developed and first practiced the specialty of orthopædic surgery in this country.

He was the grandson of Dr. John Warren, the patriot, orator, and Revolutionary surgeon, and the son of Dr. John Ball Brown; he thus had special advantages of both birth and training. When fourteen years old he suffered a fall upon the ice and for eight years was an invalid. This it was that appears to have shaped the course of his work. The lack of any surgeon possessing an orthopædic training led his father to study the subject thoroughly and to become recognized as an authority; and the son, during the long years in bed, studied his profession, and because of his infirmity had his thoughts and studies constantly turned to orthopædics. Receiving his degree in 1844, he went abroad and followed the practice of the masters, Little, Stromeyer, and Guérin, for two years. On his return he naturally inherited the orthopædic part of his father's practice. This was nearly fifteen years before Davis, Sayre, and Taylor came prominently to the front in New York. In 1861 Dr. Brown was appointed to the charge of a ward in the Home of the Good Samaritan, devoted to the treatment of deformities. This was two years before the New York Hospital for the Ruptured and Crippled was opened, and five years before the founding of the New York Orthopædic Dispensary.

Two examples may be cited which well illustrate Dr. Brown in his relations to the profession and to his patients: During the

quarter of a century which followed the first writings of Davis, Sayre, and Taylor upon the treatment of chronic joint disease, he who questioned the value of the "motion-without-friction" treatment, or ventured to neglect the use of apparatus for portative traction, risked his professional reputation, his honorable appointments, and even his good name. Yet during all this time Dr. Brown continued to treat joint disease by prolonged rest; unmoved and apparently unconscious of the epidemic delirium, he did not feel it necessary either to write in defense of his own position or to point out the absurdities and inconsistencies of those who felt the sting of his neglect. One can understand that a man the courage of whose convictions was so well founded could undertake and pursue for two years the treatment by traction and recumbency of a case of congenital dislocation at both hip joints, but to gain and hold the perfect confidence and co-operation of both mother and child so that the traction was not once relaxed and the position of the patient not once changed, evidences a man having as marvelous an influence over others as he had control over himself. Men are few who can pursue a new line of treatment in an individual case for two years without once relaxing their self confidence, but they are fewer still who, without either precedent to cite or objective progress to show, can retain the confidence of the patient and the support of the family for so long a period. Such a man was Buckminster Brown, typical of all that is best in the orthopædic surgeon: positive conviction, untiring patience, unflagging interest, fertile in expedients, careful in the details of his work, and possessed of that inestimable birthright—that *something* which makes the man loved and trusted by children.

JOHN RIDLON.

## Letters to the Editor.

### ASHEVILLE AS A WINTER RESORT.

ALEXANDRIA, EGYPT, December 18, 1891.

To the Editor of the *New York Medical Journal*:

SIR: I learn from your issue of November 21st that Dr. Karl von Ruck, proprietor of the Winyah Sanitarium for Consumptives, at Asheville, N. C., is also the observer of the United States Signal-Service Station in that city. His letter on the subject of the Asheville climate, while written in his capacity as a Government officer, seems to me to be sadly tinctured with the knowledge of the presence of another sanatorium than his own in Asheville. I hope that physicians who do not reside in Asheville, who may have spent in past years or may spend in coming years the months of January, February, and March in that resort, will come forward with their testimony as to the value of Asheville as a winter resort during those three months.

FREDERICK PETERSON, M. D.

## Reports on the Progress of Medicine.

### REPORT ON OPHTHALMOLOGY.

BY CHARLES STEDMAN BULL, M. D.

(Concluded from page 248.)

**A Case of Intracranial Neoplasm with Localizing Eye Symptoms.**  
—Oliver (*Arch. of Ophthalmol.*, xx, 1) reports the following case: A

man, aged thirty-nine years, had for two years suffered from vertigo, headaches, and momentary blindness. There was no history of traumatism, or abuse of tobacco or alcohol, or syphilis. In April, 1889, his right foot became stiff, numb, and weak. In August, 1889, some curious motor symptoms developed themselves. The right arm was adducted to the trunk, the forearm was flexed on the arm and the hand on the forearm, while the fingers remained extended. The seizures lasted from one to several minutes. These attacks became increasingly frequent, and during the attack the right leg was extended. The right grip was weak, and the right patellar tendon reflex exaggerated. Right ankle clonus was always present, and the knee clonus at times. No evidence of any mental impairment. Temperature, pressure, and muscular sense all markedly diminished on right side. Right lateral hemianopsia. On February 26, 1890, some headache and marked diminution of sight in remaining half-fields of vision. The vision was reduced to  $\frac{5}{40}$ . Direct vision for color lowered. Wernicke's hemiopic pupillary reaction sign plainly manifest on both sides. All the symptoms pointed to some disturbance in the sensory motor arc of the ocular apparatus at the base of the brain in the left optic tract, anterior to the corpora quadrigemina and posterior to the optic commissure. Retinal arteries and veins engorged on the right side. Large hæmorrhage on right optic disc. The patient died comatose on March 21st. At the autopsy the left hemisphere bulged. On horizontal section, the left lateral ventricle was shallower than the right. The left optic thalamus was indurated and swollen. Perpendicular section of the hardened mass revealed a neoplasm, involving the external portion of the left optic thalamus and corpus striatum, pinkish in color and resisting. The capsule was not invaded. The left optic tract as far as the chiasm was markedly flattened and pressed. The tumor was a glioma, with beginning sarcomatous degeneration.

**Bilateral Hemianopsia.**—Schweigger (*Arch. of Ophthalmol.*, xx, 1) reports a case of this rare affection. A man, aged seventy-five years, was suddenly attacked in September, 1888, with a hemiopic defect in both left halves of the visual fields, without the occurrence of any other symptom. The central vision was unchanged, and the ophthalmoscopic appearances were normal. In August, 1889, the right halves of the visual fields failed suddenly, as the left had done, but a small central field of vision was preserved, of twenty-two minutes in diameter. In the region of the hemiopic defects the movements of the hand were perceived eccentrically.

**The Pathological Anatomy of Panophthalmitis.**—Schöbl (*Arch. of Ophthalmol.*, xx, 1) reports a large number of cases, and summarizes as follows: A general oversight of the entire process of panophthalmitis justifies the assertion that, whether the disease be of traumatic, secondary, or metastatic origin, it commences constantly with a fulminating purulent retinitis or chorioiditis, or both together. To this is soon added a scleritis and inflammation of the capsule of Tenon, and, if the cornea has not been previously destroyed, a keratitis inducta interstitialis follows, which later assumes a suppurative character. Following this come the carnifying and hyperplastic inflammations of the various parts of the eye. The original purulent masses are gradually replaced by granulation tissue, from which later young connective tissue develops. Finally, the new-formed connective-tissue masses may undergo a cicatricial shrinking, and retrograde metamorphoses take place.

**Insufficiency of the Oblique Muscles.**—Savage (*Arch. of Ophthalmol.*, xx, 1) calls attention to the well-known function of the oblique muscles to keep the naturally vertical meridians of the two corneæ parallel even when not vertical. If there is perfect equilibrium of the obliques, this parallelism of the vertical meridians is preserved without trouble; but, if the superior oblique of either eye be too strong for its inferior, or *vice versa*, the parallelism of the vertical meridians is preserved and double vision prevented only by excessive work on the part of the weaker muscle. This brings on, at longer or shorter intervals, a train of nervous symptoms, for which at present there seems to be no hope of prevention or cure.

**The Development and Course of the Medullated Fibers in the Chiasm of the Optic Nerves.**—Bernheimer (*Arch. of Ophthalmol.*, xx, 2) has been impressed by the fact that in the optic nerve, some millimetres distant from the lamina cribrosa, the fibers appear as simple axis cylin

ders without a medullary sheath. This led him to study the development of the medullary sheath of the nerve fibers in the chiasm by means of Weigert's method of staining. The chiasm of the new-born infant is to be considered a nervous organ incompletely provided with medullated fibers; and the formation of medullary substance does not extend to the lamina cribrosa. No trace of medullary substance can be found in the chiasm, or in its roots and processes, before the twenty-ninth week of embryonic life. In the chiasm of the infant of the second or third week all the axis cylinders possess a medullary sheath in their whole extent. Careful examination of serial sections of the chiasm at this early stage will show that there are fibers in the upper half of the chiasm which pass directly from one tract to the nerve of the same side. The fact that the lower half of the chiasm contains only fibers which cross, and that the upper half contains both sorts mixed together, warrants us in assuming that the number of crossed fibers is considerably greater than the number of direct ones. The question as to whether the fibers run in a compact bundle must be answered in the negative.

**Circumvasculitis Retinæ.**—Sheffels (*Arch. of Ophthalmol.*, xx, 2) reports the case of a young blacksmith, aged eighteen, in whom congenital syphilis first manifested itself in the form of circumvasculitis of the retina of both eyes, attacking only the veins with the exception of the left v. tempor. super., leading to partial occlusion of the caliber of the vessels, enormous dilatation and very peculiar tortuosity of the terminal veins, and extensive hemorrhages. Under the inunction treatment the hemorrhages and perivascular patches are rapidly absorbed, leaving only the curious tortuosity of the veins.

**The Action of Prismospheres and Decentred Lenses.**—Percival (*Arch. of Ophthalmol.*, xx, 2) takes up the subject of the unsatisfactory action of prisms in the relief of muscular defects of the eye, and thinks this is due partly to the difficulty found in determining exactly the relative strength of the ocular muscles, and partly to a want of recognition of the precise action of prisms. In all cases in which errors of refraction exist these must first be corrected by proper lenses. Then the absolute minimum of convergence is determined by providing the patient with glasses which enable him to define some distant object without exerting his accommodation. While his attention is now concentrated on it, adducting prisms are placed before the glasses, and the strongest prism compatible with single vision enables one to discover the minimum of convergence. The exact determination of the absolute maximum of convergence is more difficult. After the examination of the refraction and the accommodation of the eyes, glasses should be given such that the near point of accommodation becomes one third of a metre. The strongest adducting prism compatible with single vision must now be found. The position of the near point of convergence can then be determined, either by the help of the tables or by means of a simple calculation. Prisms are sometimes chosen at random and ordered to be worn in the hope that they will relieve certain symptoms. Failure very often attends such unscientific treatment. There should in every case be granted a fair trial of prismospheres.

**A Prism-measure or Lens-centering Instrument.**—Smith (*Arch. of Ophthalmol.*, xx, 2) describes a new instrument devised for the purpose of centering lenses, and also for measuring the degree of a prism or prisms in lenses combined with spherical or cylindrical surfaces. The instrument consists of a bed plate, upon the front of which is fixed a degree circle, and hinged to the bed plate is an upper plate thrown up by a spring. An upright face plate stands at right angles to the upper plate. On the top of the upright face plate is a degree circle. The index finger is made of steel, and pivoted at a point to swing easily over any portion of the dial plate. In using, the lens is placed on the lower points of the surface of the bed plate. The upper plate is pressed down until its two points touch the lens, and if the lens is of the same thickness at the two points, the index finger will point to zero on the degree circle of the upright face plate. In measuring prisms, the position of the index finger will be governed by the difference of the thickness of the lens at the two points of the upper plate, and the degree of the prism will be indicated on the degree circle.

**The Proposed Methods for numbering Prisms.**—Duane (*Arch. of Ophthalmol.*, xx, 3) has calculated a table for the purpose of determining

whether the difference between the values of the deviation produced in the three different positions of the prism is sufficiently great to be of practical moment. He deduces the following facts from this table: 1. Prismatic numeration, according to the angle of minimum deviation, is sufficiently accurate when a single prism is used. 2. When, however, as in testing the adductive capacity, an aggregation of prisms whose collective refracting angle exceeds  $20^\circ$  is employed, the resulting deviation will be more than the sum of the original deviations produced by the component prisms, and must be computed by referring once more to the refracting angles of the latter. 3. When an object viewed through a converging prism, arranged in the postero-normal position, is approached to the eye, the incident ray is no longer normal to the posterior face, but becomes more nearly normal to the anterior face of the prism. Hence the deviation produced by the prism, although its position remains the same, is greater in proportion as the object approaches the eye, and when an aggregation of prisms of total refracting angle in excess of  $20^\circ$  is employed, and the object is brought very near the eye, the true convergence would be quite in excess of that calculated upon the assumption that the prism has remained in the postero-normal position, and still more in excess of the value deduced from the minimum deviating power of the prism.

**Disseminated Sclerosis, presenting the Clinical Aspect of Primary Spastic Paraplegia, with Atrophy of both Optic Nerves.**—Zimmermann (*Arch. of Ophthalmol.*, xx, 3), in reviewing the complications of the clinical features of primary spastic paraplegia exhibited by his case, calls attention to the inferior importance of all of them in comparison with the affection of the optic nerves. Atrophy of the optic nerve, when associated with the symptoms of primary spastic paraplegia, is the most valuable and reliable guide in the diagnosis of disseminated sclerosis. When observed early, before any striking appearance of other symptoms, its peculiarities will give us a hint to be on the lookout for other signs, thus enabling us to make an early and distinct diagnosis.

**Anomalies of the Ocular Muscles; an Examination of von Graefe's Doctrine of "Antipathy to Single Vision."**—Stevens (*Arch. of Ophthalmol.*, xx, 3) sets forth a view of the causation of this anomaly as follows: The condition of antipathy to single vision, as described by von Graefe and by subsequent authors, depends not upon lesion of the brain or faulty projection of the images of the retina, but upon unequal tension of corresponding ocular muscles under the influence of corresponding nerve impulses directed to them. The causation of this supposed antipathy exists mainly in two conditions. The first of these is acquired as the result of the squint operation, and consists in the fact that by unequal setting back of the insertion of the corresponding tendons, there are induced irregular responses to the impulses directed to these corresponding muscles. A second causative influence, and one which acts as an element in nearly all cases, is the difference in relative tension of muscles which act in the vertical direction.

**Report of Four Hundred and Fifty Simple Extractions of Senile Cataract.**—Greef (*Arch. of Ophthalmol.*, xx, 3) gives a résumé of the cases of cataract treated in Schweigger's clinic. One group of cases was operated upon with the Schweigger-Förster capsular forceps. Baer's broad knife, which at a distance of 30 mm. from the point is 4 mm. high, was soon supplanted with one 5 mm. high, and later still with one 7 mm. high. The section in the cornea was made upward in 117 cases. Twenty-five cases were operated on with the downward section. In the 142 cases there was perfect success in 104 cases, or 73.3 per cent., and 8 cases of loss, or 5.6 per cent. Two of these losses should be excluded, as the cases were complicated with irregular astigmatism from old corneal leucomata, and with chorioiditis at the macula. In the remaining six cases the loss was due as follows: In one case to hemorrhage into the anterior chamber immediately after the operation; in two cases to irido-chorioiditis, secondary cataract, posterior synecchia, and thickening of the iris; in one case to prolapse of iris, followed by irido-cyclitis; in three cases to infectious infiltration of the lips of the wound. Prolapse of the iris occurred in nine cases, and in eight of them the iris was cut off. Prolapse of vitreous is one of the chief anatomical conditions after which prolapse of iris may be expected; therefore, wherever this accident is probable, as in high degrees of myopia, fluidity of the vitreous, etc., it is best to perform the operation with iridectomy. From

his own records, neither Schweigger nor his assistant, Greef, can furnish any satisfactory statistics as to whether prolapse of the iris is oftener seen after the upward or downward section. As regards the technique of the simple operation, much more care is needed in the first few hours than after the old operation, and most operators are agreed in avoiding the least movement of the patient after the extraction of the lens. The patient must be comfortably put to bed, and remain there as quietly as possible for three full days. The bandage is renewed on the second day, but the eye is not to be inspected till the third or fourth day. Atropine may be dropped into the inner corner of the closed lids as long as may be necessary.

**Glaucoma and Affections of the Optic Nerve.**—Schweigger (*Arch. of Ophthalm.*, xx, 4) has here a general "critique" on the subject of glaucoma. He considers that it is now conceded by everyone that cases of excavation reaching to the margin of the disc are not uncommon where the skilled touch has been unable to detect any trace of increased tension. The candid observer must admit that increase of intra-ocular pressure must be carefully considered in the light of other diagnostic evidence. Augmented tension and glaucoma are by no means identical conditions. Increase of tension may be doubtful or altogether absent in cases where glaucoma was certainly present. There is no such thing as a standard of hardness by which the tension of all eyes can be determined. There are eyes that are physiologically hard and eyes that are physiologically soft. If we inquire into the conditions under which excavations occur in glaucoma, we must begin with a study of the physiological excavation. Our knowledge of the physiological leads us to an appreciation of the pathological. Schweigger defines the term "physiological excavation" to be one which includes more than one third of the disc surface, and whose floor is formed by the lamina cribrosa. There may be slight variations in breadth and depth. When there is joined to this pre-existing physiological excavation an optic-nerve atrophy, the difficulties of diagnosis are greatly increased. He feels convinced that all cases described as glaucoma simplex fulminans are really instances of atrophic degeneration of the optic nerve occurring with physiological cupping of the disc. If this is true, there is no such thing as a typical excavation due to intra-ocular pressure. Leaving the questions of tension and excavation of the disc and coming to a consideration of other symptoms, he considers the cloudy cornea as an inflammatory œdema, but without anything characteristic about it. As regards the condition of the pupil, he believes that glaucoma may progress to complete loss of sight, without any interference with the mobility of the iris. The dilatation of the iris in glaucoma with inflammatory symptoms he regards as of the greatest diagnostic value. It rarely happens that the pupil is enlarged and at the same time round and perfectly movable. In most cases this enlargement of the pupil may be regarded merely as a ciliary paralysis from pressure. The arterial pulsation so often met with is the result of a disproportion between the intravascular pressure in the arteria centralis and the vitreous pressure. Usually the cause of the phenomenon lies in increased intra-ocular tension, but this is not always the case. He considers arterial tension alone as insufficient evidence of glaucoma. In Schweigger's opinion, the diagnostic value of the halo glaucomatosus is very small. He considers that the course of the disease is marked by distinct attacks of increased tension that come on and again subside. A most important consideration is that the inflammatory symptoms of glaucoma are not the cause but the results of increased tension. The ciliary body is undoubtedly the locality in which the sympathetic secretion of glaucoma takes place. The only road to success in diagnosis lies in continued observation. As soon as the existence of glaucoma has been demonstrated, iridectomy should be performed at the earliest opportunity. When glaucoma malignum attacks one eye, it follows iridectomy on the other eye, even when the second eye is not affected for years after the first. In all cases of chronic glaucoma affecting both eyes it is advisable to operate first of all upon the worse eye, even if it be absolutely blind. Should this be followed by the normal healing process, the second eye may be operated without the least apprehension. As soon as an iridectomy has been performed on a genuine case of glaucoma, we may regard it as certain that the disease has been brought to a standstill. The instances in which this is not true are so extremely rare that they do not carry much weight.

**Papilloma of the Conjunctiva.**—S. Fuchs (*Arch. of Ophthalm.*, xx, 4) thinks that a better name for this disease would be "fibroma papillare," for in many cases the epidermoid or epithelial strata make up no small part of the tumor, particularly in those papillary fibromata which develop as a plate or skin-like mass of connective tissue. A study of the genesis of these tumors always shows that they really belong to the class of fibrous growths, and that the small amount of fibrous tissue present is due to the fact that there has been a retrograde metamorphosis or an atrophy, caused by the excessive development of the epithelial constituent. In the initial stage all these papillary growths appear as a small, round knot due to excessive development of the superficial tissue; vessels push into the connective-tissue center of the little bud, and at the same time the epithelial layer grows thicker. New sprouts appear on the bud and become vascular, forming finally a branched papilla. The papillomata which spring from the tarsal conjunctiva often assume a cauliflower appearance, with a wide base. Similar forms of less extent are seen on the plica semilunaris. Those developing on the ocular conjunctiva and in the fornix are, on the contrary, branched pedunculated vegetations with a papillary surface. Fibroma papillare of the sclero-corneal border, in its initial stage, can hardly be distinguished clinically from epithelioma; but, when it has reached a certain development and overlaps the cornea, the infiltration or non-infiltration of the substance of the cornea is a diagnostic sign of great value, for a papilloma which overlaps the cornea may be lifted up and pushed back to the conjunctiva, but an epithelioma will infiltrate the corneal substance and rest immovably on it. Another valuable point is the enlargement of the neighboring lymphatic glands, which never occurs in papilloma. The papillomata of the limbus are distinguished from so-called "spring catarrh" by their softness and their papillary surface. Papillomata are benign, although inclined to recur if not radically removed.

**Pulsating Exophthalmia.**—Wing (*Arch. of Ophthalm.*, xx, 4) reports the case of a man, aged twenty-two, who, in August, 1889, fell some distance, striking on his head, and was carried in an unconscious condition to a hospital. He remained unconscious for twenty-four hours, and was discharged in ten days apparently well. In December, 1889, the right eye began to protrude, and continued to do so till June, 1890. At that time the lids could scarcely be closed over it. Vision was  $\frac{2}{30}$ . There was a distinctly pulsating tumor at the upper and inner angle of the orbit. There had never been any pain. By pressure the eye could be made to partly recede. Pressure on the common carotid artery caused the pulsations to cease. There had probably been a fracture at the base, passing across the cavernous sinus and causing a communication between it and the internal carotid artery, thereby forcing arterial blood into the ophthalmic veins, causing the great distention and strong pulsation. The common carotid was ligated, and the pulsations ceased at once and have never returned. Fourteen months later there was scarcely a trace of the exophthalmia, and vision was  $\frac{2}{30}$  +.

**The Shapes and Development of the Pigment Cells of the Chorioid.** Rieke (*Archiv für Ophthalm.*, xxxvii, 1) draws the following conclusions from his investigations:

1. All the pigment is formed within the cells.
2. The shape of the pigment cells is manifold, ranging from almost round to those with many processes. The latter are the most frequent in the anterior parts of the chorioid.
3. The arrangement of the cells, as a rule, corresponds to the course of the blood-vessels.
4. The clumps of pigment are perhaps to be regarded partly as permanent processes, partly as the remains of disintegrated cells.
5. The diffused pigment granules seem to owe their minute subdivision to the disintegration of former pigment cells.
6. In many animals the newly born show a marked pigmentation of the stroma cells of the chorioid.
7. The earliest appearance of pigmentation in the human chorioid occurs in the seventh month of fetal life.
8. The pigment cells of the chorioid do not originate in the pigmented wandering cells, but rather in the fixed connective-tissue cells.

**Sarcoma of the Uveal Tract.**—Freudenthal (*Arch. für Ophthalm.*,

xxxvii, 1) lays down the following propositions in regard to the development and growth of sarcoma of the uveal tract: There are four stages, viz.: 1. The stage of amblyopia or of the non-irritating course of the disease, where there is more or less disturbance of vision and slight changes in the fundus, but no symptoms of inflammation. 2. The glaucomatous or inflammatory stage. Here the intra-ocular tension is increased, and there are symptoms of internal and external irritation. 3. The stage of formation of fungous or episcleral nodules. The tumor has here perforated the capsule of the eyeball, and developed externally to it. 4. The stage of so-called constitutional generalization, or appearance of metastatic growths in other organs of the body.

**Primary New Development of Hairs on the Intermarginal Edge of the Eyelids as the Usual Cause of Trichiasis.**—Raehlman (*Arch. für Ophthalm.*, xxxvii, 2) has concluded, from clinical observation and microscopical examination, that long-continued hyperæmia of the blood-vessels of the edge of the lid causes a proliferation of the epithelial stratum (*stratum Malpighii*), which, after it has reached a certain height, often causes the development or *new* formation of hairs and sebaceous glands on the edge of the eyelid.

**Septic Keratitis.**—Silvestri (*Arch. für Ophthalm.*, xxxvii, 2), in his investigations, has never been able to observe and demonstrate the entrance of cocci or of leucocytes containing cocci into the anterior chamber. In well-marked cases of induced panophthalmitis he has never been able to demonstrate the exit of any cocci beyond the immediate zone of inoculation. He has also satisfied himself that the cocci, even when inclosed within the white blood-corpuscles, are still living and capable of active proliferation.

**The Infection and Disinfection of Collyria.**—Franke (*Arch. für Ophthalm.*, xxxvii, 2) draws the following conclusions from his investigations: Chemical disinfection of collyria is generally a better means of sterilization than that by boiling. For this purpose he recommends sublimate solutions (1 to 5,000 and 1 to 10,000); cyanide of mercury (1 to 1,000 and 1 to 5,000); resorcin, 1 per cent.; carbolic acid, 0.5; boric acid, 4 per cent. in carbolic acid 1 per cent.; Panas's solution; and thymol. It is not possible to produce an antiseptic effect with the antiseptics under discussion in a solution of the strength which can be used in the eye. A solution of sublimate (1 to 10,000) will in half an hour, however, render a solution of atropine or cocaiue aseptic. For eserine, an addition of resorcin is preferable.

**The Channels of Exit of the Aqueous Humor.**—Staderini (*Arch. für Ophthalm.*, xxxvii, 3) formulates his conclusions as follows: 1. The aqueous humor comes from the posterior chamber, and enters the anterior chamber through the pupil. 2. The current of the aqueous humors extends slowly and homogeneously from the pupil toward the angle of the anterior chamber in a radiating manner. Rotary phenomena in this current never occur. 3. We find in the canal of Fontana the anatomical and physical conditions which facilitate the exit of the aqueous humor through filtration into the venous channels at the sclero-corneal region. An open communication between the anterior chamber and the vascular system does not exist. 4. From the canal of Fontana fine rifts or channels extend into the tissue of the sclera, which partly follow the course of the deeper veins at the sclero-corneal region, and partly lose themselves in the lymphatic system of the sclera. Similar rifts extend from the canal of Fontana into the connective tissue stroma of the ciliary body and root of the iris. 5. It can not be doubted that the iris participates in the absorption of corpuscular elements from the anterior chamber. The anatomical structure of the anterior layer of the iris tissue is fully capable of active absorption. 6. Physostigmine hastens and atropine retards in a very marked degree the absorption from the anterior chamber.

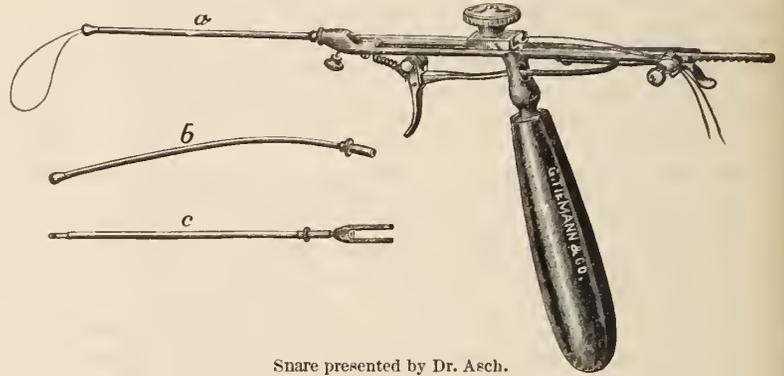

**The Anatomy of Pinguecula.**—Fuchs (*Arch. für Ophthalm.*, xxxvii, 3) gives the following results of his investigations: A pinguecula consists of a thickening of the conjunctiva, accompanied by a hyaline degeneration of the tissue elements, and the deposit of free hyaline. The cause of this degeneration is found in the senile changes of the tissue, to which must be added the influence of external irritation.

The same conditions lead in the cornea to similar hyaline degeneration (arcus senilis, band-shaped corneal opacity, yellow patches in corneal scars). Another important change of the conjunctiva at the site of the pinguecula consists in an enormous increase in size and number of the elastic fibers, for which there is no analogy in any other organ in the body.

## New Inventions, etc.

### PRESENTATION OF INSTRUMENTS AT THE THIRTEENTH MEETING OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION.

A *laryngeal forceps* was exhibited by Dr. Mulhall. "The instrument is the well-known forceps of Morell Mackenzie, modified to meet certain contingencies. The case for which it was designed was one of laryngeal papillomata attached to the lower surface of the vocal cords, in a deeply situated larynx, requiring the use of long blades. It was found that when the blades, from the angle to the laryngeal ends, were made of the requisite length—three inches and three quarters to four inches—the cutting lips could not be made to approximate accurately. To overcome this, a joint was made in each blade, half an inch from the

Snare presented by Dr. Asch.

angle, and the result I show you is an instrument whose lips approximate perfectly. The instrument will be made, on order, by Hohlkamp, Grady, & Moore, 915 Olive Street, St. Louis, Mo."

A *snare*, combining many of the features of instruments already well known, was presented by Dr. Morris J. Asch.

## Miscellany.

**Recent Investigations regarding Favus.**—Dr. George D. Holsten, of Brooklyn, contributes the following on this subject:

In the *New York Medical Journal* for July 11, 1891, a *résumé* was given of the results of investigation on the fungus of favus up to that time. Since then further studies have been made.

Louis P. Frauk (*Monatshefte f. prak. Dermatol.*, March 15, 1891), working in Unna's laboratory in Hamburg, has applied all the resources of modern bacteriological technique to determine the following questions: 1. Is the favus of animals and man the same? 2. Are there different forms of human favus fungus; also of animal favus fungus? 3. Should it be proved that different forms of favus fungi exist, which of them is to be regarded as the true form, and are the others separate forms or only varieties?

He examined four pure cultures of favus from the human being and two cultures of mouse favus. As the mouse favus is not so well known as the human favus, he describes it. "The entire head from snout to neck was covered with thick, dirty gray-white crusts, the eye

of one mouse being completely overgrown. There were several isolated scutella in the neighborhood of the shoulders and some small ones on the back. The shoulder blades were not invaded by the disease, as they are said to be in many cases." He excised skin and crusts, hardened in alcohol, and prepared sections.

From these six cultures three forms were isolated, whose characteristics are briefly described as follows: 1. Both mouse favi. Growth, which begins on the second or third day, is superficial and feathery white, the border of the colonies radiating, the under surface dark gray, with a yellowish shimmer. The diameter of the mycelia measured 1.8 to 4  $\mu$ , running in long striæ and terminating in sharp tips. 2. Fungi of cultures Nos. 2 and 4 (known as Form II) of human favus, which macroscopically and microscopically seemed identical, showed a markedly slower growth, did not extend in so superficial a manner as the first, but rather grew in depth. Colonies, especially the older ones, in chalk-like masses, were, on the lower surface, of a deep golden color, with shading toward brown. Mycelia measured 2.0 to 5.0  $\mu$ ; branches short and at right angles, terminations clubbed, pear-shaped and branched, or chandelier-like. This he considers identical with Quincke's  $\gamma$  favus. 3. Fungi of cultures Nos. 1 and 3 (known as Form III) were likewise identical. Growth slower than that of mouse favus, but more rapid than Form II; border rather cloud-like than radiating; superficially mealy, under surface deep golden. Diameter of mycelia 2.5 to 5.0  $\mu$ , and microscopically resembling the mouse favus.

Culture I inoculated on his arm was followed twenty-six days after by a patch resembling that of herpes tonsurans; the periphery was dark red and covered with small vesicles, which, drying into sero-yellow crusts, were generally situated around the mouths of hair follicles. Mycelium and spores were found microscopically in the hairs and crusts. After two months the favus patch spontaneously passed away.

Recultures from this gave a positive result on one black mouse; negative results on three white mice. The experimental cycle was as follows: Favus from a mouse was cultivated on agar, then inoculated on his arm, producing a "favus herpeticus"; from the hairs and crusts cultures were again made, and these inoculated on a black mouse gave positive results.

Culture I was also inoculated directly on several white and gray mice; after five days a beautifully formed yellow scutellum of the size of a small pea developed on one white mouse; the rest negative.

Culture II on mice and himself gave negative results.

Culture III on himself showed appearances very similar to the mouse favus, except that the patch did not attain so great a size, nor was the periphery so clearly marked. Examination of hairs gave the same results.

The forms discovered are then compared with those of other investigators. Form II agreed with Quincke's  $\gamma$  fungus and the mouse favus with the  $\alpha$  fungus, but none of Quincke's descriptions agreed with Form III.

Grawitz's description corresponds with Frank's II and with Quincke's  $\gamma$ , and seems to be the one most often met with. Grawitz describes the colonies as growing in herds of lentil size, round, becoming later on dry, with a whitish or straw-yellow center, and thereby becoming very similar to the scutellum as seen on the skin.

Fabry, in his interesting experiments, employed a fungus which he declared to be identical with the  $\gamma$  fungus. Some of the specimens placed at the disposal of Frank proved to be the same as Form II.

Münnich's cultures correspond with Grawitz's. Microscopically, Frank found them like Quincke's  $\gamma$  and his own Form II.

Jadassohn, in his demonstration of favus cultures, showed that they were identical with Quincke's  $\gamma$  form, and also with the one described by Grawitz.

Verujski, in photographs taken on the seventeenth and forty-second day of cultivation, showed a fungus identical with Form II.

Elsenberg's Variety 1 resembles Quincke's  $\alpha$  fungus, especially the macroconidia; Variety 2 is like the  $\gamma$  fungus in growth.

The fungus of Král, which Piek considers the achorion, did not correspond to any of Frank's. If this be proved also to be a true favus fungus, then there are three, possibly four forms: 1. Quincke's  $\gamma$  fungus,

identical with Frank's II, the fungus found by all the recent investigators (Quincke, Grawitz, Fabry, Münnich, Jadassohn, Verujski, Elsenberg, Unna, and v. Sehlen), and from which by inoculation Quincke, Grawitz, and Fabry obtained positive results, but Frank only negative. 2. Form I (or mouse) favus of Frank, with positive inoculation results. 3. The III fungus with positive results. 4. Král's achorion, from which Piek obtained positive results.

Frank thinks there are different forms of fungi for animals and man, still it remains for further investigators to prove if one or the other form predominates. The possibility of the conveyance of mouse favus to human beings he thinks can not be doubted, a matter of great interest from a hygienic point of view.

Kaposi (*Internat. klin. Rundschau*, 1891, Nos. 13 and 15) reiterates his former opinion that there is a difference between the fungus of favus and herpes tonsurans, but does not accept the views of recent investigators that different forms of favus fungi may exist.

V. Mibelli (*La Riforma med.*, 1891, Nos. 69 and 79, quoted in *Monatsch. f. prak. Derm.*, September 1, 1891) gives the results of his studies on favus in Sardinia, where the disease is very prevalent and severe. He arrives at the following conclusions: 1. Only one single species of fungus can produce favus. 2. This fungus produces the common as well as the herpetic favus. 3. The different appearances of colonies and the morphological differences of cultures are dependent on age and on culture media, and various other causes. 4. The variety of ways in which cultures develop depends upon the stage of growth and source of the original seed from which the new vegetation arises. 5. To such differences in origin and development are probably attributable the various pictures of favus herpeticus and favus vulgaris, as well as other transitional forms.

To the third of the questions which Frank propounded—should it be proved that different forms of favus fungi exist, which of them is to be regarded as the true form, and are the others separate forms or only varieties?—no answer could be made, for the reason that, clinically, only one favus disease has so far been recognized. Further investigations will have to consider if there may not be more than one form of the disease, and this question Dr. P. Unna considers in a paper entitled *Three Forms of Favus*, read before the Dermatological Section of the Society of German Scientists and Physicians, in Halle, September 24, 1891, and published in the *Monatshefte f. prak. Derm.*, January 1, 1892.

During the past summer Unna studied in his laboratory, in company with Dr. Frank, the three forms of favus fungi which the latter isolated and cultivated. He also experimented with some ten samples of material, two of which he received from Scotland, two from Holland, and one from Italy, and expresses the opinion that there may be more different forms of favus than were ever thought could exist, but confines the results of his experiments to Frank's three forms alone.

In order to establish positively which is the true favus fungus, it will be necessary to produce on animals and man scutella which shall correspond to the disease as developed spontaneously; and also that it shall run a subacute or chronic course.

Frank inoculated on his arm cultures of Form I (mouse favus), and obtained a beautiful, scaly, strongly reddened ring, with small vesicles and yellow points around the hair follicles. That these were true favus growths was proved by recultivating on proper media and reinoculating on a black mouse, when typical scutella resulted. That this favus herpeticus was not a traumatic dermatitis was shown by the fact that the symptoms did not appear until three weeks after inoculation.

Inoculations with Form III also produced on Frank a red, scaly patch, in the scales and hairs of which favus fungi were visible, but recultivations were not successful. Therefore further experiments were made on Dr. Williams, who inoculated Cultures I and III on his right leg. Inflammatory reaction appeared on the third day on Culture I; on the fourth several very small vesicles appeared, and on the fifth swelling and pain were strongly marked. On the sixth day thick yellow crusts began to form, pain became very severe, and locomotion was impossible. Form III ran a similar, but much slower and milder, course, the inflammation beginning on the fourth day.

On the ninth day both cultures were nearly the same, except that in Form I the crusts were much thicker. Removal of crusts revealed thin,

shining, red epidermis; no more vesiculation. Extraction of hairs very painful; crusts contained many spores but little mycelium, a few spores in extracted hairs.

On the ninth day all crusts were washed off with hot water, whereupon pain subsided. Small yellow points, generally but not always around the hair follicles, remained. Thin scales then began to form which in the course of three weeks became typical scutella of pepper-corn to pea size.

It was now of interest to note that these two favus patches lying close to each other on the same region of the skin on the same individual should be unlike each other and remain so. These differences are as follows: 1. Scutella of I less numerous and less concentric than III; some scutella of I being a half ring, while III shows a disposition to assume the full, round, saucer-like form. 2. Favus I is of gray-yellow color, while III is a dark sulphur color. The first resembles the gray-yellow color of mouse favus. 3. Scutella of I much softer and more friable than III. The latter permitted of being removed *in toto*, while the former would break in pieces. 4. Scutella I more firmly attached to the horny layer than III, which also increased the difficulty of removal. Adding to these, 5, the more rapid development of reaction; 6, the greater inflammatory symptoms, especially at the beginning; and 7, the greater amount of pain in Favus I, then the differences between the two become sufficiently great to clinically separate them.

These two forms, I and III, are illustrated by a beautiful chromolithograph.

Favus II was also inoculated on Dr. Williams, but, owing to an accident, did not develop.

Later Dr. Douglas inoculated Favus II and some Scotch favus received from Edinburgh. The II developed some ring-shaped, faintly reddened patches, which remained six weeks, scaled, and then spontaneously disappeared. Cultures were not obtained.

Dr. Leslie Roberts was the fifth and Unna the sixth person to inoculate themselves with Favus II.

This Favus II, with thick, short, septated mycelia, forked chandelier-like terminations, clubbed ends and spores, resembles Quincke's  $\gamma$  favus, the favus of Grawitz, Fabry, Verujski, Jadassohn, Mibelli, and the second variety of Elsberg.

Inoculations were made on white and black mice, on rats, guinea-pigs, rabbits, cats, and chickens, with the three forms of favus. Good scutella were never developed on white mice and rats, black rats, and chickens. The best success was obtained on rabbits and guinea-pigs; in a second degree on black mice and cats; at the same time there is a difference in the vulnerability of different animals to the three forms of favus. Form I develops best on mice and rabbits; form II on guinea-pigs; and III again on rabbits.

The scutella were then examined microscopically. They were composed mainly of the fungus with some of the epidermic cells intermixed; resting on the basal horny membrane, at the beginning they were covered above and at the sides with the superficial and middle layers of the horny epidermis, but later on were free. They did not, as some investigators have said, invade the entire epidermis and cutis. The lower portion of the scutella grows rapidly, the sides less so, while the upper portion not at all or but very little. As the lower portion in growing meets with the resistance of the epidermis, it is compelled to push out at the sides, while above, the suspension of growth tends to draw the sides toward the center, causing the characteristic cup-shape. This is true whether the growth occurs around a hair follicle, on non-hairy surfaces, or on culture media, and also occurs with other fungi which have a similar growth.

Favus I on rabbits and mice showed a very rich and regular insertion of the root ends of the mycelia into the horny layer, where they did not branch, but were straight. Here the mycelia were parallel, very little branched, grew strongly upward, and formed voluminous scutella. The proliferation of oidium spores was very rich and regular, becoming with age thicker and larger in the center.

Favus II on guinea-pigs showed a less regular and rich insertion of the root ends. They were often forked on implantation, and bent into a hooked form. The further development of the mycelia was a less parallel one than in Favus I; more bent, more often branched, and grew less strongly in height, whereby the scutella became less volu-

minous. On the other hand, the deeper mycelia showed a desire when around a hair to reach the depths of the follicle. Proliferation of oidium spores not so abundant and regular as in Favus I.

Favus III on rabbits showed a great upward growth from the horny layer, but it was not straight as in I, nor in such rounded bent lines as in II, but rather in peculiar knotty branches with many sharp corners. The very small amount of spore formation also distinguished this from Favus I. Branching in the depths of hair follicles took place, but not so regularly as in Favus II.

A division of favus into scutella and herpes favus, as Quincke proposed, seems to Unna not feasible; then each form of favus can give a variety of pictures, according to the skin on which it grows, to surrounding circumstances, as foreign fungi which hinder the growth, formation of crusts and scales, erythema, vesicles, and from the reaction of the skin it may be destroyed.

As a result of these investigations, Unna believes he has demonstrated three characteristic species of fungi, which are capable of developing typical favus scutella on animals and man.

He proposes for the fungus of Favus I the name *Achorion euthytrix* (meaning with straight or parallel filaments); and for the disease produced by this fungus the name *Favus griseus*, from the gray-yellow color of the scutella. (*Griseus*—apothecary's Latin; *Favus rarus*—gray-yellow—would be more classical, but not so well understood.) Fungus II he names *Achorion dikroon* (not dichroon), on account of the forked terminations; and the disease *Favus sulfuricus tardus*, from the sulphur-yellow color and the slow growth. Fungus III he proposes to call *Achorion atakton*, on account of the irregular mycelia processes; and its disease, *Favus sulfuricus celerior*, from the yellow color of the scutella and its somewhat rapid growth.

That other investigators have reached results differing from the foregoing due to their not having inoculated apparently different forms side by side, either on skin or on culture plates. The best culture medium Unna considers one composed of agar, four per cent.; peptone, one per cent.; levulose, five per cent.; salt, one half per cent.

In a postscript to the above-mentioned article the results of further inoculations with the II form (*Favus sulfuricus tardus*) are given. On non-hairy human skin, after eight inoculations, only erythematous papules were produced; therefore Unna considers that this form is only capable of producing on non-hairy adult skin a short-lived superficial disease, a so-called favus herpeticus. Nevertheless, it is a true favus for human beings; then it was bred from the scutellum from a child's head. On the mouse, on the other hand, good results were achieved. Differing from the gray-yellow, rough scutellum of *Favus griseus* and the small, dish-shaped ochre-yellow of *Favus sulfuricus celerior*, this scutellum is of a white-yellow or cream-color, has a smooth, finely folded upper surface, and a leather-like shine. Small particles of this scutellum gave on cultures the *Favus sulfuricus tardus*.

Noticing that scutella were most often seen around the muzzle of captured mice, Unna discontinued artificial inoculations and fed the mice with the old agar-peptone-levulose cultures, and in this manner arrived at better results.
